Abstract. This paper addresses the problem of planning the motion of one or more pursuers in a polygonal environment to eventually “see” an evader that is unpredictable, has unknown initial position, and is capable of moving arbitrarily fast. This problem was first introduced by Suzuki and Yamashita. Our study of this problem is motivated in part by robotics applications, such as surveillance with a mobile robot equipped with a camera that must find a moving target in a cluttered workspace.

A few bounds are introduced, and a complete algorithm is presented for computing a successful motion strategy for a single pursuer. For simply-connected free spaces, it is shown that the minimum number of pursuers required is $\Theta(\sqrt{n})$. For multiply-connected free spaces, the bound is $\Theta(\sqrt{n} + \log n)$ pursuers for a polygon that has $n$ edges and $h$ holes. A set of problems that are solvable by a single pursuer and require a linear number of recontaminations is shown. The complete algorithm searches a finite cell complex that is constructed on the basis of critical information changes. It has been implemented and computed examples are shown.

1 Introduction

The general problem addressed in this paper is an extension or combination of problems that have been considered in several contexts. Interesting results have been obtained for pursuit-evasion in a graph, in which the pursuers and evader can move from vertex to vertex until eventually a pursuer and evader lie in the same vertex [16, 19]. The search number of a graph refers to the minimum number of pursuers needed to solve a pursuit-evasion problem, and has been closely related to other graph properties such as cutwidth [15, 17]. Pursuit-evasion scenarios in continuous spaces have arisen in a variety of applications such as air traffic control [1], military strategy [10], and trajectory tracking [9]. Although interesting decision problems arise through the differential motion models, geometric free-space constraints are usually not considered in classical pursuit-evasion games. Once these constraints are introduced, the problem inherits the additional complications that arise in geometric motion planning.

A region of capture is often associated with a pursuit-evasion problem, and the “capture” for our problem is defined as having the evader lie within a line-of-sight view from a pursuer. A moving visibility polygon in a polygonal environment adds geometric information that must be utilized, and also leads to
connections with the static art gallery problems [18, 21]. In the limiting case, art
gallery results serve as a loose upper bound on the number of pursuers by allowing
a covering of the free space by static guards, guaranteeing that any evader
will be immediately visible. Far fewer guards are needed when they are allowed
to move and search for an evader; however, the required motion strategies can
become quite complex. A closely related art gallery variant is the watchman tour
problem [4]. In this case a minimum-length closed path is computed such that
any point in the polygon is visible from some point along the path. In our case,
however, the pursuers have the additional burden of ensuring that an evader
cannot “sneak” to a portion of the environment that has already been explored.
The problem that we consider and other variations have been considered previ-
ously in [5, 22]. It was stated in [21] that it remained an interesting challenge to
determine if a polygon is searchable by a single pursuer.

Several applications can be envisioned for problems and motion strategies of
this type. For example, suppose a building security system involves a few mobile
robots with cameras or range sensors that can detect an intruder. A patrolling
route can be automatically computed that guarantees that any mobile intruder
will eventually be found. To optimize expenses, it would also be important to
know the minimum number of robots that would be needed. Applications are
not necessarily limited to adversarial targets. For example, the task might be
to automatically locate another mobile robot, items in a warehouse or factory
that might get moved during the search process, or possibly even people in a
search/rescue effort. Such strategies could be used by automated systems or by
human searchers.

2 Problem Definition

The pursuers and evader are modeled as points that translate in a polygonal
free space, \( F \). Let \( e(t) \in F \) denote the position of the evader at time \( t \geq 0 \). It is
assumed that \( e : [0, \infty) \to F \) is a continuous function, and the evader is capable
of moving arbitrarily fast. The initial position \( e(0) \) and the path \( e \) are assumed
unknown to pursuers. Any region in \( F \) that might contain the evader will be
referred to as contaminated, otherwise it will be referred to as cleared. If a region
is contaminated, becomes cleared, and then becomes contaminated again, it will
be referred to as recontaminated.

Let \( \gamma^i(t) \) denote the position of the \( i^{th} \) pursuer at time \( t \geq 0 \). Let \( \gamma^i \) represent
a continuous path of the \( i^{th} \) pursuer of the form \( \gamma^i : [0, \infty) \to F \). Let \( \gamma \) denote a (motion) strategy, which refers to the specification of a continuous path for
every pursuer: \( \gamma = \{ \gamma^1, \ldots, \gamma^N \} \).

For any point, \( q \in F \), let \( V(q) \) denote the set of all points in \( F \) that are visible
from \( q \) (i.e., the linear segment joining \( q \) and any point in \( V(q) \) lies in \( F \)). A strategy, \( \gamma_i \), is a solution strategy if for every continuous function \( e : [0, \infty) \to F \)
there exists a time \( t \in [0, \infty) \) and an \( i \in \{1, \ldots, N\} \) such that \( e(t) \in V(\gamma^i(t)) \). This implies that the evader will eventually be seen by one or more pursuers,
regardless of its path. Let $H(F)$ represent the minimum number of pursuers for which there exists a solution strategy for $F$.

Section 3 presents some bounds on $H(F)$ for classes of free spaces, and also shows that some polygons for which $H(F) = 1$ only admit solutions that require a linear number of recontaminations. Section 4 addresses the problem of computing a solution strategy, $\gamma$, for a given $F$.

3 Worst-Case Bounds

Several new bounds are presented in this section. For a simply-connected free space, $F$, with $n$ edges, it is shown that $H(F) = \Theta(\lg n)$. For a free space, $F$, with $h$ holes, it is shown that $H(F) = \Omega(\sqrt{h} + \lg n)$ and $H(F) = O(h + \lg n)$. For the class of problems in which $H(F) = 1$, it is shown that the same region can require recontamination as many as $O(n)$ times. This result is surprising because pursuit-evasion in a graph is known not to require any recontaminations [11].

Consider the problem of determining the minimum number of pursuers, $H(F)$, required to find an evader in a given free space $F$. This number will generally depend on both the topological and geometric complexity of $F$. In [22] a class of simple polygons is identified for which a single pursuer suffices (referred to as “hedgehogs”). For any $F$ that has at least one hole, it is clear that at least two pursuers will be necessary; if a single pursuer is used, the evader could always move so that the hole is between the evader and pursuer. In some cases subtle changes in the geometry significantly affect $H(F)$.

Consider $H(F)$ for the class of simply-connected free spaces. Let $n$ represent the number of edges in the free space, which is represented by a simple polygon in this case. A logarithmic worst-case bound can be established:

**Theorem 1.** For any simply-connected free space $F$ at worst $H(F) = O(\lg n)$.

**Proof:** The proof is built on the following observation. Suppose that two vertices of $F$ are connected by a linear segment, thus partitioning $F$ into two simply-connected, polygonal components, $F_1$ and $F_2$. If $H(F_1) \leq k$ and $H(F_2) \leq k$ for some $k$, then $H(F) \leq k + 1$ because the same $k$ pursuers can be used to clear both $F_1$ and $F_2$. This requires placing a static $(k + 1)^{th}$ pursuer at the edge common to $F_1$ and $F_2$ to keep $F_1$ cleared after the $k$ pursuers move to $F_2$ (assuming arbitrarily that $F_1$ is cleared first).

In general, if two simply-connected polygonal regions share a common edge and each can be cleared by at most $k$ pursuers, then the combined region can be cleared by at most $k + 1$ pursuers. Recall that for any simple polygon, a pair of vertices can always be connected so that polygon is partitioned into two regions, each with at least one third of the edges of the original polygon [3]. This implies that $F$ can be recursively partitioned until a triangulation is constructed, and each triangular region only requires $O(\lg n)$ recombinations before $F$ is obtained (i.e., the recursion depth is logarithmic in $n$). Based on the previous observation and the fact that each triangular region can be trivially searched by a single pursuer, $H(F) = O(\lg n)$. $\square$
The remaining question for simply-connected free spaces is whether there actually exist problems that require a logarithmic number of pursuers. Some results from graph searching will first be described and utilized to construct difficult worst-case problem instances. Let Parsons' problem refer to the graph-searching problem presented in [16, 19]. The task is to specify the number of pursuers required to find an evader that can execute continuous motions along the edges of a graph. Instead of using visibility, capture is achieved when one of the pursuers "touches" the evader. Let $G$ represent a graph, and $S(G)$ represent the number of needed pursuers, referred to as the search number of $G$.

The following lemma implies that a geometric realization of any planar graph instance can be constructed:

**Lemma 2.** For every planar graph, $G$, there exists a polygonal free space $F$ such that Parsons' problem on $G$ is equivalent to the visibility-based pursuit evasion problem on $F$.

**Proof:** Consider a planar representation of $G$ in which linear segments correspond to the edges. Each linear segment can be replaced by a corridor of sufficient length as shown in Figure 1, with $\epsilon > 0$ chosen such that no pair of corridors intersect. Portions of the corridor edges can be removed at corridor junctions to prevent overlap.

![Diagram](image)

**Fig. 1.** Second-order visibility between the two entrances is not maintained.

It remains to establish that searching the environment constructed by the network of bent corridors is equivalent to searching a planar graph. If a solution strategy for Parsons' problem is specified as an ordered set of traversed edges for each pursuer, then traversing the corresponding corridors will clearly solve the geometric problem. Consider a given solution for the geometric problem. If the pursuers move from junction to junction without reversing within a corridor, then traversing the equivalent edges also solves the planar graph problem. For the geometric problem, a static pursuer can be placed in a corridor (as in position $a$ in Figure 1), allowing two other pursuers to clear the corridor from each end without leaving the junctions unguarded. In this case and in similar cases, the pursuer that is fixed in the geometric problem can clear the corresponding edge by traveling between its endpoints in $G$; thus, the graph problem can still be solved using the same number of pursuers. □

This theorem, from [19], is useful for proving Theorem 4:
Lemma 3. (Parsons) Let G be a tree. Then $S(G) = N + 1$ if and only if there exists a vertex in G whose removal separates G into three components, $G_1$, $G_2$, and $G_3$, such that $S(G_i) \geq N$ for $i \in \{1, 2, 3\}$.

Theorem 4. There exist simply-connected free spaces $F$ with $n$ edges such that $H(F) = \Omega(\lg n)$.

Proof: Using Lemma 3, a tree, $G$, can be constructed recursively that has a constant branching factor of three, height $N - 1$, and requires $N$ pursuers (an example is given in [19]). By Lemma 2, an equivalent geometric instance can be constructed for any $N$. □

Figure 2.a shows an example, which relies on Lemma 3. Theorem 1 and Theorem 4 together imply a tight logarithmic bound, $H(F) = \Theta(\lg n)$.

Next consider the class of problems for which $F$ has $h$ holes.

Fig. 2. a) An instance from a sequence of simply-connected free spaces that require $\Omega(\lg n)$ pursuers. b) An instance from a sequence of problems that requires a number of pursuers that is at least proportional to the square root of the number of holes.

Theorem 5. For any free space $F$ with $h$ holes at worst $H(F) = O(\sqrt{h} + \lg n)$.

Proof: Divide the pursuers into two groups: $O(\sqrt{h})$ pursuers will be used to reduce the polygon to simply-connected components, and $O(\lg n)$ pursuers will be used to clear each component. Construct an arbitrary triangulation of $F$. Let a trichromatic triangle be defined as a triangle that touches three distinct connected components of the boundary of $F$. Using at most $O(h)$ trichromatic triangles, $F$ can be partitioned into simply-connected components whose boundaries are comprised of the boundary of $F$ and edges of trichromatic triangles. To establish this, form a planar graph by placing a vertex in each hole of $F$ and one vertex outside of $F$. For every trichromatic triangle edge joining two
boundaries, form an edge for this graph by joining the vertices corresponding to these boundaries by a path along the trichromatic edge, in the obvious way. From the planarity of this graph we can easily argue that the overall number of trichromatic edges, and therefore of trichromatic triangles, is \( O(h) \).

Consider the dual graph of the triangulation, which has \( O(n) \) edges and vertices. Take the subgraph induced by taking only the vertices that correspond to trichromatic triangles in the original triangulation. The planar graph separator theorem \([14]\) implies that at most \( O(\sqrt{h}) \) edges can be chosen to partition the graph into two portions with at least one third of the edges on each side of the partition. Each edge in the induced subgraph corresponds to a simply-connected region of \( F \) that can be cleared with \( O(\log n) \) pursuers by Theorem 1. In fact, the same set of pursuers can be used for each simply connected component. The \( O(\sqrt{h}) \) pursuers then form a barrier that maintains the cleared areas obtained by other pursuers on either side, much in the same way as the partitioning edges in the proof of Theorem 1. The planar graph separator theorem can be applied recursively to the remaining portions of \( F \) on either side of a barrier, and the free space can be cleared using the same progression as for Theorem 1. At the \( i^{th} \) level of recursion, at most \( \frac{2}{3} \) as many pursuers will be needed to form a barrier in comparison to the \((i-1)^{th}\) level of recursion. The free space is reduced to simply-connected components that can be cleared using \( O(\log n) \) pursers. The total number of pursers needed to form barriers is

\[
O(\sqrt{h} + \sqrt{\frac{2}{3}h} + \sqrt{\frac{4}{3}h} + \cdots) = O(\sqrt{h}).
\]

Thus, \( F \) can be cleared using at most \( O(\sqrt{h} + \log n) \) pursers. □

Figure 2.6 shows an illustrative example of the following theorem:

**Theorem 6.** There exist free spaces \( F \) with \( h \) holes such that \( H(F) = \Omega(\sqrt{h} + \log n) \).

**Proof:** For any positive integer \( k \), a planar graph of cutwidth \( k \) can be constructed using \( O(k^2) \) vertices and edges. Recall that the cutwidth, \( CW(G) \), is the minimum cutwidth taken over all possible linear layouts of \( G \). A linear layout of \( G \) is a one-to-one function mapping the vertices of \( G \) to integers, and the cutwidth for a particular layout is the maximum over all \( i \) of the number of edges connecting vertices assigned to integers less than \( i \) to vertices assigned to integers as large as \( i \). Define a sequence of planar graphs, \( G_1, G_2, \ldots \). Let the vertices of \( G_k \) correspond to the set of all points with integer coordinates, \( (i, j) \), such that \( 0 \leq i, j \leq k \). Let the edges of \( G_k \) connect any two vertices for which one coordinate differs by one unit (i.e., a standard four-neighborhood). The cutwidth of \( G_k \) is \( k \).

It is established in \([15]\) that for all graphs \( G \), the search number \( S(G) \) is related to the cutwidth as \( S(G) \leq CW(G) \leq \left\lceil \frac{\text{deg}(G)}{2} \right\rceil \cdot S(G) \), in which \( \text{deg}(G) \) is the maximum vertex degree of \( G \). Since \( \text{deg}(G_k) = 4 \), \( S(G_k) \leq k \leq 2S(G_k) \). Using Lemma 2, geometric instances of \( G_k \) can be constructed. Both \( G_k \) and each geometric instance require \( O(k) \) pursuers. There is a quadratic number of holes in each geometric instance; hence, \( H(F) = \Omega(\sqrt{h}) \). This corridor structure
can be combined with the structure from Theorem 4 to yield an example that requires $\Omega(\sqrt{k} + \lg n)$ pursuers. □

Theorem 6 and Theorem 5 together imply a tight bound, $H(F) = \Theta(\sqrt{k} + \lg n)$. The final theorem of this section pertains to the class of free spaces that can be searched by a single pursuer. A similar result is also obtained in [5]. It states that there exist examples that require recontaminating some portion of the free space a linear number of times. This result is surprising because for Parsons’ problem it was shown in [11] that no recontamination is necessary (a shorter proof of this appears in [2]). In [22] a free space was given that requires two recontaminations, which at least established that recontamination is generally necessary for visibility-based pursuit evasion. Theorem 7 establishes that a linear number of recontaminations can be needed, and it still remains open to determine whether the number of recontaminations can be bounded from above by a polynomial, which would imply that the problem of deciding whether $H(F) = 1$ lies in $NP$.

**Theorem 7.** There exists a sequence of simply-connected free spaces with $H(F) = 1$ such that $\Omega(n)$ recontaminations are required for $n$ edges.

**Proof:** It will be shown that the example in Figure 3 requires $k - 2$ recontaminations by visiting the point $a \in F$ a total of $k - 1$ times to repeatedly clear the “peak.” Without loss of generality, consider the set of strategies that can be specified by identifying the sequence of points, $a, b_1, \ldots, b_k, c_1, \ldots, c_k$, that are visited. Assume that the shortest-distance path is taken between any pair of points. Consider visiting $b_i$ for some $1 < i < k$, followed by a visit to another “leg”, say $b_j$ (or $c_j$). If any legs between $b_i$ and $b_j$ are contaminated, then $b_i$ will get contaminated, which undoes previous work. If all legs are initially contaminated, then they must be visited in one of two orders: $(b_1, c_1, b_2, c_2, \ldots, b_k, c_k)$ or $(b_k, c_k, b_{k-1}, c_{k-1}, \ldots, b_1, c_1)$. Because of symmetry, consider visiting the legs from left to right without loss of generality. Assume that the peak is initially contaminated. The points $b_1$ and $c_1$ can be visited to clear the leftmost set of legs; however, these will get contaminated when $b_2$ is visited. By traveling from $c_1$ to $a$ to $b_2$, the leftmost set of legs remains cleared because the peak is cleared. When $c_2$ is visited, the leftmost three legs remain cleared; however, the peak becomes recontaminated. Thus, $a$ will have to be visited again before clearing $b_3$. By induction on $i$ for $1 < i \leq k$, the peak will have to be cleared by visiting $a$ each time between visits to $c_i$ and $b_{i+1}$. This implies that $a$ will be visited $k - 1$ times, resulting in $k - 2$ recontaminations. □

### 4 Computing a Solution Strategy

Section 4.1 defines a general information space (or space of knowledge states) for this problem, and provides a general method for partitioning the information space into equivalence classes, which can reduce the general problem to finite cell searching. NP-hardness is also established in Section 4.1. Section 4.2 presents a
Fig. 3. A linear number of recontaminations is required. Although this polygon can be searched by a single pursuer, the peak must be visited $k-1$ times.

A complete algorithm for the case in which $H(F) = 1$ that computes a solution strategy by decomposing $F$ into convex cells based on edge visibility. This algorithm is quite efficient in practice, and was used to compute the examples shown in Section 5.

4.1 General Concepts

A complete algorithm must compute a solution strategy for a given number of pursuers, if such a strategy exists. It is natural to compare the notion of completeness for this problem to completeness for the basic motion planning problem (i.e., the algorithm will find a collision-free path if such a path exists).

One important difference, however, is that the minimum number of pursuers is crucial, but does not have a correspondence for the basic path planning problem. A variety of simple, heuristic algorithms can be developed that might use more pursuers than necessary.

The general problem is intractable if $P \neq NP$:

**Theorem 8.** Computing $H(F)$ is NP-hard.

**Proof:** It is shown in [17] that Parsons’ problem for a planar graph with maximum vertex degree 3 is NP-complete (i.e., computing the search number, $S(G)$). By Lemma 2, equivalent geometric instances can be constructed, which implies that computing $H(F)$ is NP-hard. \(\square\)

This significantly reduces hopes that an efficient algorithm can be determined for the general problem. A complete algorithm for $H(F) = 1$ is detailed in this paper, and the general techniques apply to the case in which $H(F) > 1$. In related work [13] we have developed a greedy algorithm that efficiently solves many multiple-pursuer problems.
Because the position of the evader is unknown, one does not have direct access to the state at a given time. This motivates the consideration of an information space that identifies all unique situations that can occur during the execution of a motion strategy. Let a state space, \( X \), be spanned by the coordinates \( x = (x^1, \ldots, x^N) \), in which \( x^i \) for \( 1 \leq i \leq N \) represents the position of the \( i^{th} \) pursuer, and \( x^e \) represents the position of the evader. Since the positions of the pursuers are always known, let \( X^p \) denote the subspace of \( X \) that is spanned by the pursuer positions, \( x^p = (x^1, \ldots, x^N) \).

It will be useful to analyze a strategy in terms of manipulating the set of possible positions of the evader. Let \( S \subseteq F \) represent the set of all contaminated points in \( F \). Let \( \eta = (x^p, S) \) for which \( x^p \in X^p \) and \( S \subseteq F \) represent an information state. Let the information space, \( I \), represent the set of possible information states. The information space is a standard representational tool for problems that have imperfect state information, and has been useful for other motion planning problems [6, 12].

For a fixed strategy, \( \gamma \), a path in the information space will be obtained by \( \eta(t) = (\gamma^1, \ldots, \gamma^N, S(t)) \) in which \( S(t) \) can be determined from an initial \( S(0) \) and the trajectories \( \{\gamma^i(t')\} \in [0,t] \) for each \( i \in \{1, \ldots, N\} \). Let \( \Psi(\eta, \gamma, t_0, t_1) \) represent the information state that will be obtained by starting from information state \( \eta \) and applying the strategy \( \gamma \) from \( t_0 \) to \( t_1 \). The function \( \Psi \) can be thought of as a “black box” that produces the resulting information state when a portion of a given strategy is executed.

We next describe a general mechanism for defining critical information changes. This is inspired in part by a standard approach used in motion planning, which is to preserve completeness by using a decomposition of the configuration space that is constructed by analyzing critical events. For example, in [20] a cell decomposition is determined by analyzing the contact manifolds in a composite configuration space that is generated by the positions of several disks in the plane.

The next definition describes an information invariance property, which allows the information space, \( I \), to be partitioned into equivalence classes. A connected set \( D \subseteq X^p \) is conservative if \( \forall \eta \in I \) such that \( x^p \in D \) and \( \forall \gamma : [t_0, t_1] \rightarrow D \) such that \( \gamma \) is continuous and \( \gamma(t_0) = \gamma(t_1) = x^p \), then the same information state, \( \eta = \Psi(\eta, \gamma, t_0, t_1) \), is obtained. This implies that the information state cannot be altered by moving along closed paths in \( D \). Just as in the case of motions in a conservative field, the following holds:

**Theorem 9.** (Path invariance) If \( D \) is conservative then for any two continuous trajectories, \( \gamma_1, \gamma_2 \), mapping into \( D \) such that \( \gamma_1(t_0) = \gamma_2(t_0) \) and \( \gamma_1(t_1) = \gamma_2(t_1) \) then \( \Psi(\eta, \gamma_1, t_0, t_1) = \Psi(\eta, \gamma_2, t_0, t_1) \), for any \( \eta \).

**Proof:** Select any third continuous trajectory, \( \gamma_3 : [t_0, t_1] \rightarrow D \), such that \( \gamma_3(t_0) = \gamma_1(t_1) \) and \( \gamma_3(t_1) = \gamma_1(t_0) \) (i.e., heading in the opposite direction). Form a new trajectory, \( \gamma_{132} \), by concatenating the trajectories \( \gamma_1, \gamma_3, \) and \( \gamma_2 \). The resulting information state will be \( \Psi(\eta, \gamma_1, t_0, t_1) \) because \( \gamma_3 \) followed by \( \gamma_2 \) forms a closed-loop path, and thus yields the same information state by conservativity of \( D \). Note that \( \gamma_1 \) followed by \( \gamma_3 \) is also a closed-loop path, which
implies that \( \gamma_2 \) must bring the information state from \( \eta \) to \( \Psi(\eta, \gamma_1, t_0, t_1) \). Hence, 
\[
\Psi(\eta, \gamma_1, t_0, t_1) = \Psi(\eta, \gamma_2, t_0, t_1). \quad \Box
\]

Thus, the information state from moving between \( \xi_1^p \in D \) and \( \xi_2^p \in D \) is invariant with respect to the chosen path. This partitions the information space into equivalence classes. Within is each class the particular chosen path is insignificant, which leads to a finite graph search problem.

### 4.2 A Complete Algorithm for a Single Pursuer

Since the general problem is NP-hard, it is worth focusing on the complete algorithm for the case of a single pursuer. The basic idea is to partition the free space into convex cells that maintain completeness, and perform a search on the resulting quotient information space. This algorithm has been implemented and tested on a variety of examples, two of which are shown in Section 5.

Suppose the pursuer is at a point \( q \in F \). Consider the circular sequence of edges in the resulting visibility polygon. The edges generally alternate between bordering an obstacle and bordering free space. Let each edge that borders free space be referred to as a *gap edge*. Consider associating a binary label with each gap edge. If the portion of the free space that borders the gap edge is contaminated, then it is assigned a "1" label; otherwise, it is assigned a "0" label indicating that it is clear. Let \( B(q) \) denote a binary sequence that corresponds to labelings that were assigned from \( q \in F \). Note that the set of all contaminated points is bounded by a polygon that must contain either edges of \( F \) or gap edges from the visibility polygon of the pursuer. Thus, the specification of \( q \) and \( B(q) \) uniquely characterizes the information state.

Consider representing the information state using \( q \) and \( B(q) \), and let a pursuer move in a continuous, closed-loop path that does not cause gap edges to appear or disappear at any time. Each gap edge will continuously change during the motion of the pursuer; however, the corresponding gap edge label will not change. The information state cannot change unless gap edges appear or disappear. For example, consider the problem shown in Figure 4 which shows a single pursuer that is approaching the end of a corridor. If the closed-loop motion on the left is executed, the end of the corridor remains contaminated. This implies that although the information state changes during the motion, the original information state is obtained upon returning. During the closed-loop motion on the right, the gap edge disappears and reappears. In this case, the resulting information state is different. The gap label is changed from "1" to "0".

Hence, a cell decomposition that maintains the same corresponding gap edges will only contain conservative cells. The idea is to partition the free space into convex cells by identifying critical places at which edge visibility changes. A decomposition of this type has been used for robot localization in \([8, 23]\), and generates \( O(n^3) \) cells in the worst case for a simple polygon (which is always true if \( H(F) = 1 \)). The free space can be sufficiently partitioned in our case by extending rays in the three general cases. Obstacle edges are extended in either direction, or both directions if possible. Pairs of vertices are extended outward
only if both directions are free along the line drawn through the pair of points. This precludes the case in which one direction cannot be extended; although edge visibility actually changes for this case, it does not represent a critical change in information.

The next issue is searching the information space for a solution, which corresponds to specifying a sequence of adjacent cells. The solution strategy must take the form of a path that maps into $F$. This can be constructed by concatenating linear path segments, in which each segment connects the centroids of a consecutive pair of cells in the sequence.

The cells and their natural adjacency relationships define a finite, planar graph, $G_c$, referred to as the cell graph. Vertices in $G_c$ are generally visited multiple times in a solution sequence because of the changing information states. For each vertex in $G_c$, a point, $q \in F$, in the corresponding cell can be identified, and the labels $B(q)$ can be distinct at each visit. Initially, the pursuer will be in some position at which all gap labels are “1”. The goal is to find any sequence of cells in $G_c$ that leave the pursuer at some position at which all gap labels are “0”.

A directed information state graph, $G_I$, can be derived from $G_c$, for which each vertex is visited at most once during the execution of a solution strategy. For each vertex in $G_c$, a set of vertices are included in $G_I$ for each possible labeling of the gap edges. For example, suppose a vertex in $G_c$ represents some cell $D$, and there are 2 gap edges for $B(q)$ and any $q \in D$. Four vertices will be included in $G_I$ that all correspond to the pursuer at cell $D$; however, each vertex represents a unique possibility for $B(q)$: “00”, “01”, “10”, or “11”. Let a vertex in $G_I$ be identified by specifying the pair $(q, B(q))$.

To complete the construction of $G_I$, the set of edges must be defined. This requires determining the appropriate gap labels as the pursuer changes cells. Suppose the pursuer moves from $q_i \in D_i$ to $q_j \in D_j$. For the simple case shown in the lower right of Figure 4, assume that the gap edge on the left initially has

\[ \text{Contaminated} \]

\[ \text{Without crossing a critical boundary} \]

\[ \text{Crossing a critical boundary} \]

**Fig. 4.** A critical event in the information space can only occur when edge visibility changes.
a label of “0” and the gap edge on the right has a label of “1”. Let the first bit
denote the leftmost gap edge label. The first transition is from “01” to “0”, and
the second transition is from “0” to “00”. The directed edges in $G_I$ are $(q_i, “01”)$$
leads to $(q_j, “0”)$, $(q_j, “00”)$. In the case of multiple gap edges, correspondences must be determined to
correctly compute the gap labels. In general, if any $n$ gap edges are merged, the
Corresponding gap edges will receive a “1” label if any of the original gap edges
contain a “1” label. Once the gap edge correspondences have been determined,
the information state graph can be searched using Dijkstra’s algorithm with
an edge cost that corresponds to the distance traveled in the free space by
the pursuer. Unfortunately, the precise complexity of the complete algorithm
cannot be determined. In the worst-case, examples can be constructed that yield
an exponential number of information states, but it is not clear whether these
information states necessarily have to be represented and searched to determine
a solution (it is not even known if optimal-length solutions to the single-pursuer
problem can be verified in polynomial time).

5 Computed Examples

The complete algorithm is implemented in C++ and executed on an SGI
Indigo2 workstation with a 200 MHz MIPS R4400 processor. Most problems we
encountered were solved in a few seconds or less. The implementation uses the
quad-edge structure from [7] to maintain the topological ordering of the conservative
cells. The search strategy is Dijkstra’s shortest path algorithm, in which
the distance is measured from the adjacent cell centroids. Figure 5 shows two
computed examples. We have also computed solutions for the example shown in
Figure 3, the hookpin example described in [22] that requires two recontamina-
tions, and several other problems.

6 Conclusions

We proved some new bounds and introduced a complete algorithm for the polygon
searching problem. A logarithmic bound on the number of needed pursuers
was shown for the case of simply-connected free spaces, and a square-root bound
was expressed in terms of the number of holes for multiply-connected free spaces.
It was also shown that there exist problems requiring a linear number of recon-
taminations. A few open problems remain, such as determining tight bounds
on the number of pursuers for general polygons, and determining whether a
polynomial-time algorithm exists to decide whether $H(F) = 1$. The complexity
of our complete algorithm also remains open. It also remains an interesting pur-
suit to attempt to characterize the set of simple polygons such that $H(F) = 1$;
interesting subsets have been characterized in [22], and our information space
concepts might be useful in this endeavor.

Information space concepts were used to provide a natural characterization
of the unique problem states. The visibility-based pursuit-evasion problem was
Fig. 5. Two computed examples are shown, each with three snapshots of the solution. The black area represents the contaminated region, and the white area represents the cleared region. The thick curve shows a portion of computed trajectory, which is continued in each frame. The shaded region indicates the visibility region at the final time step of the indicated portion of the trajectory. The thin lines in the cleared region indicate the cell boundaries.

established as NP-hard. The general concept of partitioning the information space on the basis of critical information changes was introduced to develop a complete algorithm. For the case in which \( H(F) = 1 \), the complete algorithm was implemented and tested on several examples.
