

On Comparing the Power of Robots

Jason M. O’Kane and Steven M. LaValle*

Abstract

Robots must complete their tasks in spite of unreliable actuators and limited, noisy sensing. In this paper, we consider the *information requirements* of such tasks. What sensing and actuation abilities are needed to complete a given task? Are some robot systems provably “more powerful,” in terms of the tasks they can complete, than others? Can we find meaningful equivalence classes of robot systems? This line of research is inspired by the theory of computation, which has produced similar results for abstract computing machines. Our basic contribution is a dominance relation over robot systems that formalizes the idea that some robots are stronger than others. This comparison, which is based on the how the robots progress through their *information spaces*, induces a partial order over the set of robot systems. We prove some basic properties of this partial order and show that it is directly related to the robots’ ability to complete tasks. We give examples to demonstrate the theory, including a detailed analysis of a limited-sensing global localization problem.

1 Introduction

Suppose we want a robot to complete some task, such as navigating to a goal, manipulating an object, or localizing itself within its environment. Many different combinations of sensing and motion modalities have been used to complete each of these tasks. Indeed, much of the robotics literature is concerned with finding *sufficient conditions* on the sensing and actuation capabilities needed to complete such tasks. In this paper we take a different approach. For a given task, we are interested in determining the *necessary conditions*: What sensors and actuators are needed? What are the *information requirements* of robotic tasks? The long-term goal of this research is to develop a theory of robots and sensing that helps in answering such questions. Answers to these questions are important because we expect that a deep understanding of the difficulty of tasks in terms of their information requirements will lead to simpler and less expensive robot designs.

This work is inspired in part by the theory of computation, which begins with precisely defined models of abstract machines, such as finite automata, Turing machines, and so on [Hopcroft et al., 2000, Sipser, 1997]. In this context, a *problem* is usually a language of strings; to solve the problem is to accept strings in this language and reject all others. The theory of computation gives answers to several kinds of basic questions about these machines and problems.

1. *Solvability*: Can a given machine solve a given problem?
2. *Complexity*: If the machine can solve the problem, how efficiently (in terms of time or space, for example) can it do so?
3. *Comparison*: Are some machines strictly more powerful, in terms of the problems they can solve, than others? It is known, for example, that pushdown automata can accept a strictly larger set of languages than can finite automata. Likewise, Turing machines are more powerful than pushdown automata.

LaValle are with the Department of Computer Science, University of Illinois at Urbana-Champaign, 201 North Goodwin Avenue, Urbana, IL 61801, USA. Email: {jokane, lavalle}@cs.uiuc.edu. Fax: +1-217-265-6591

4. *Equivalence*: Are there apparently dissimilar machines that can solve the same set of problems? For example, it is a standard result that a Turing machine with multiple tapes is functionally equivalent to an ordinary single-tape Turing machine. Less obviously, Turing machines and recursive functions have been shown to have equivalent computation power.

These ideas are well understood. In the sense that they form the formal foundation of the discipline, they are part of the core of computer science. Current robotic science lacks a comparable foundation; the field needs a unified theory in which meaningful statements can be made about the complexity of robotic tasks and the robot systems we build to complete these tasks.

Can we adapt standard models of computation to the robotics context? Unfortunately, these models are fundamentally ill-suited for studying robotics problems, because they assume that all of the relevant information is supplied ahead of time on the machine’s tape. Sensing and uncertainty are central, defining issues in robotics; this structure is destroyed by an *a priori* encoding of the problem on a machine’s tape. Traditional models of online computation [Sleator and Tarjan, 1985, Karp, 1992, Borodin and El-Yaniv, 1998] are also inadequate, because they assume that some fixed encoding of the problem is revealed incrementally. In contrast, robotics problems are generally interactive, in the sense that the robot’s decisions influence the information that becomes available in the future. Others study robotics problems using similar tools [Gabriely and Rimon, 2004, Papadimitriou and Yannakakis, 1991], but do not explicitly consider the effects of varying sensing and motion capabilities.

The aim of this paper is to develop a “sensor-centered” theory for analyzing and comparing robot systems. The central idea we present is a notion of *dominance* of one robot model over another. In informal terms:

A robot R_2 *dominates* another robot R_1 if R_2 can “simulate” R_1 , collecting at least as much information as R_1 .

We make three primary contributions in developing this idea. First, we present the idea of *robotic primitives* for modeling robot systems as collections of independent components. A single robotic primitive represents a self-contained “instruction set” for the robot that may involve sensing, motion, or both. A robot model is defined by a set of primitives that the robot can use to complete its task. By selecting a “catalog” of primitives from which complete robot systems are constructed, we effectively determine a set of robot systems to consider. For clarity, we define these models in an idealized setting in which time is modeled as a series of discrete stages and the robot has perfect knowledge of its environment, perfect control, and perfect sensing. Second, we give a definition for dominance of one robot system over another that formalizes the imprecise definition above. This definition is based on comparing reachability in a *derived information space* [LaValle, 2006]. By mapping sensor-action histories from a variety of robots into the same derived information space, we can compare the abilities of these robots in a concrete, formal way. We prove some basic properties of this dominance relation and give some examples, including a detailed investigation of the global localization problem. Third, we demonstrate the generality of our ideas by showing how to remove several of the simplifying assumptions we make in the initial presentation.

Our approach is based on two main ideas.

1. *Information spaces*: Traditional planning methods focus on the robot’s progression through a space of states. What happens when the state is hidden and sensing thereby becomes relevant? One approach is to use *state estimation*, in which the robot uses the information available to it to make an “educated guess” about its state. The robot can treat this estimated state as its true state and ignore the uncertainty. In some extremely limited contexts this is provably optimal (see for example, Section 6.1 of Bertsekas [2001]). We, however, are interested in a broader class of tasks for which accurate state estimation is impossible.

The relevant space for such problems is the robot’s *information space*. This space fully describes the information available to the robot, including its initial condition, the history of actions it has applied, and the history of sensor observations it has received. The robot’s “state” in this space is always fully known. Information spaces originated in game theory [Kuhn, 1953], but have been used in robotics for some time [Barraquand and Ferbach, 1995, LaValle and Hutchinson, 1998, Erdmann, 1993, Goldberg and Mason, 1990, LaValle, 2006].

2. *Tradeoffs expressed as partial orders:* We present a partial order defining the *dominance* of one robot system over another. The definition is based in turn on another partial order, an *information preference relation* over information space, that indicates which information states are preferred to others. Although these relations admit the possibility that no meaningful comparisons can be made, we find this desirable: physical tasks and robot systems exhibit complex relationships and tradeoffs that can potentially defy meaningful linear ordering.

The challenge of robotics lies in the interactions between sensing, actuation, and computation. In this paper, we focus the effects of varying choices for the robot’s sensing and actuation capabilities. The robot’s computational abilities (as measured, for example, by processing power or memory limitations) are also relevant, but we do not consider them here.

The remainder of this paper is organized as follows. Section 2 reviews related research. Section 3 lays a foundation of basic definitions for robotic planning problems. Section 4 introduces the concept of robotic primitives and defines the set of robots induced by a catalog of primitives. In Section 5, we describe the information preference relation. The definition of dominance and some basic properties thereof appear in Section 6. In Section 7, we apply the results from Sections 4-6 to the global localization task. In Section 8, we present several generalizations our basic results to account for environment uncertainty, imperfect control and sensing, and continuous time. Section 9 discusses the limitations of this work and describes some open problems.

Preliminary versions of this work appear in O’Kane and LaValle [2006] and O’Kane and LaValle [2007a].

2 Related work

Our approach can be viewed as *minimalist* in the sense that we are interested in solutions that use sensing sparingly. The minimalist approach in robotics has a long history, dating perhaps to Whitney [1986]. Minimalist approaches have been used in manufacturing contexts for part orientation [Agarwal et al., 2001, Akella et al., 2000, Erdmann and Mason, 1988, Goldberg, 1993, Goldberg and Mason, 1990, Moll and Erdmann, 2002, van der Stappen et al., 2000, Wiegley et al., 1997] and in mobile robotics for navigation and exploration [Acar and Choset, 2001a, Choset and Burdick, 1995, Kutulakos et al., 1994, Kamon et al., 1999, Lumelsky and Tiwari, 1994, Ó. Dúnlaing and Yap, 1982, Tovar et al., 2004].

Our goals are similar to those of Donald [1995]. The reductions in that work are similar to our dominance relation; Donald’s notion of calibration is related to our idea of initial conditions. The most fundamental difference is that our analysis is rooted in the information space. We claim that for robotic problems in which sensing is a crucial issue, the information space is the space in which the problem can most naturally be posed. The work of Erdmann [1995] is grounded in the preimage planning ideas due to Lozano-Pérez, Mason, and Taylor [1984]. In Erdmann’s work, sensors are modeled by giving a partition of state space. The problem of sensor design is to choose a partition so that from each region in the partition, the robot knows what action to select in order to make progress toward its goal. Others in artificial intelligence [Brafman et al., 1998] and control theory [Abate et al., 2006, Egerstedt, 2002, Girard and Pappas, 2005] have addressed related issues.

Although the examples in this paper use nondeterministic uncertainty, which is based on set membership, the basic structure of our analysis is compatible with probabilistic uncertainty models like those of Thrun et al. [2005]. Many probabilistic methods (for example, Austin and Jensfelt [2000] or Lenser and Veloso [2000]) can be characterized as operating in an information space whose members are probability distributions over state space. Our methods can be viewed as axiomatic because they can be applied in any situation that satisfies the definitions of Sections 3-5. In this sense, the model of uncertainty used is orthogonal to the questions addressed in this work.

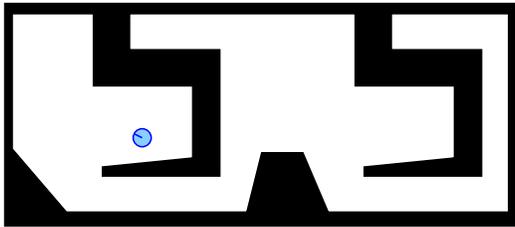

Figure 1: A robot in a planar environment E . Its state space is $X = E \times S^1$.

3 Basic definitions

This section presents basic definitions for robotic planning problems. To keep the presentation as clear as possible, we make several simplifying assumptions here and show in Section 8 how to relax them.

3.1 States, actions, and observations

We allow a robot to move in a state space X . Many of the examples in this paper are for a point robot with orientation in the plane. In these examples, we use $X = E \times S^1$, in which $E \subset \mathbb{R}^2$ is the robot's environment and $S^1 = [0, 2\pi]/\sim$, where \sim is an equivalence relation identifying 0 and 2π , represents the robot's orientation. Note that this formulation encodes the geometry of the robot's environment into its state space. Situations in which the environment is unknown can be modeled using a richer state space, as described in Section 8.1. In general, however, we allow arbitrary state spaces, including configuration spaces and phase spaces of physical systems.

Time proceeds in variable-length *stages*, indexed by consecutive integers starting with 1. In each stage, the robot selects an action u from its action space U and moves to a new state according a state transition function $f : X \times U \rightarrow X$. At the conclusion of each stage, the robot's sensors provide an observation y from an observation space Y , according to $h : X \times U \rightarrow Y$. Call h the robot's *observation function*. Let x_k , u_k , and y_k denote respectively the state, action, and observation at stage k . These sequences are related to each other by f and h :

$$x_{k+1} = f(x_k, u_k) \tag{1}$$

$$y_k = h(x_k, u_k). \tag{2}$$

Although we are assuming in this section that both state transitions and observations are deterministic, we acknowledge that in realistic contexts, managing unpredictability in motion and sensing is a crucial issue. We omit such uncertainty here because of the additional complications it would introduce. The extensions needed to relax this assumption are introduced in Section 8.

For convenience, we also define an iterated version of f that applies k actions in succession:

$$f(x, u_1, \dots, u_k) = f(\dots f(f(x, u_1), u_2) \dots, u_{k-1}), u_k). \tag{3}$$

The robot's capabilities are modeled in the action and observation sets U and Y and in the maps f and h that interpret these sets. See Figure 2. A *robot model* is a 5-tuple (X, U, Y, f, h) giving values to each of these elements.

3.2 Information spaces

Although the robot does not know its state, it does have access to the history of actions it has selected and observations it has made. The space of such histories is the robot's *history information space* (history

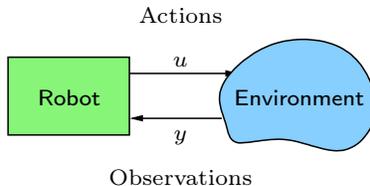

Figure 2: The robot interacts with its environment by executing actions and receiving observations.

I-space), denoted \mathcal{I}_{hist} :

$$\mathcal{I}_{hist} = \bigcup_{i=0}^{\infty} (U \times Y)^i. \quad (4)$$

After k stages, the robot’s *history information state* (history I-state) is a sequence of length $2k$:

$$\eta_k = (u_1, y_1, \dots, u_k, y_k). \quad (5)$$

We occasionally abuse notation by writing $(\eta_k, u_{k+1}, y_{k+1})$ for the history I-state formed by appending u_{k+1} and y_{k+1} to η_k . How is the state space related to the robot’s history I-space? One connection is by way of the notion of states consistent with an I-state:

Definition 1 *A state $x \in X$ is consistent with a history I-state $\eta_k = (u_1, y_1, \dots, u_k, y_k)$ if there exists some $x_1 \in X$ such that $x = f(x_1, u_1, \dots, u_k)$ and $y_j = h(f(x_1, u_1, \dots, u_{j-1}), u_j)$ for each $j = 1, \dots, k$. \circ*

The intuition is that a state x is consistent with an I-state η_k if a robot having I-state η_k might possibly be at state x .

We may define a *policy* $\pi : \mathcal{I}_{hist} \rightarrow U$ over history I-space. Note that, given a state x_k and a history I-state η_k , the history I-states reached by repeatedly executing π are fully determined. As a shorthand, we define a function F that applies a policy several times in succession, so that m applications of a policy π , starting at state x_k and information state η_k , lead to a new history I-state given by

$$\eta_{m+k} = F^m(\eta_k, \pi, x_k). \quad (6)$$

Note that $F^m(\eta_k, \pi, x_k)$ depends on the true state x_k (which is unknown to the robot) because x_k influences the observation sequence the robot receives.

The history I-space is not particularly useful by itself. For pairs of robots whose action or observation spaces differ, the history I-spaces also differ, making the history I-space unhelpful for comparing robots. Therefore, we select a *derived information space* (derived I-space) \mathcal{I} and an *information mapping* (I-map) $\kappa : \mathcal{I}_{hist} \rightarrow \mathcal{I}$. Informally, an I-map computes a “compression” or “interpretation” of the history I-state. If the history I-spaces of several robot models are mapped to the same derived I-space \mathcal{I} , then the robots can be compared by examining their progression through \mathcal{I} . In principle, we may select \mathcal{I} and κ arbitrarily. The usefulness of a derived I-space lies in its ability to capture the information relevant to the task of interest.

Example 1 *We define the nondeterministic I-space \mathcal{I}_{ndet} , in which derived I-states are nonempty subsets of X . The interpretation is that the robot’s derived I-state is the minimal set guaranteed to contain the true state. For any history I-state η , the nondeterministic derived I-state $\kappa_{ndet}(\eta)$ is the set of states consistent with η . Equivalently, the I-map $\kappa_{ndet} : \mathcal{I}_{hist} \rightarrow \mathcal{I}_{ndet}$ can be defined recursively:*

$$\kappa_{ndet}(\cdot) = X \quad (7)$$

$$\kappa_{ndet}(\eta, u, y) = \{f(x, u) \mid x \in \kappa_{ndet}(\eta), y = h(x, u)\} \quad (8)$$

Note that in Equation 7, we assume the robot initially has no information about its state. \diamond

An important special case is the value of κ for an empty history, that is, $\kappa(\cdot)$. This value gives an *initial condition* for the robot, reflecting any knowledge the robot may have before its execution begins.

A *task* for the robot is a goal region $\mathcal{I}_G \subseteq \mathcal{I}$ in derived I-space that the robot must reach. This notion is a generalization of the traditional idea of a goal state or goal region in state space. A *solution* is a policy π under which, for any $x \in X$, there exists some l such that $F^l(\eta_1, \pi, x) \in \mathcal{I}_G$.

4 Defining a set of robot systems

In this section we discuss how a set of robots can be defined in terms of a set of independent components.

4.1 Robotic primitives

At the most concrete level, a robot is a collection of motors and sensors connected to some sort of computer. Between these components there may be interactions via open- or closed-loop controls. We abstract this complexity by defining the notion of a *robotic primitive*. Each robotic primitive defines a “mode of operation” for the robot. When primitives are implemented, they may draw on one or more of the robot’s physical sensors or actuators. Every kind of motion or sensing available to the robot must be modeled as a robotic primitive. Robotic primitives correspond roughly to the *oracles* that appear in the theory of computation [Sipser, 1997, Soare, 1987], in the sense that they provide the ability to make certain transitions and collect certain observations, without specifying how these abilities are implemented.

Formally, we define robotic primitives in terms of the action and observation abilities they provide.

Definition 2 A robotic primitive (or simply a primitive) P_i is a 4-tuple

$$P_i = (U_i, Y_i, f_i, h_i) \tag{9}$$

giving an action set U_i , an observation set Y_i , a state transition function $f_i : X \times U_i \rightarrow X$, and an observation function $h_i : X \times U_i \rightarrow Y_i$. ◦

Let $\mathcal{RP} = \{P_1, \dots, P_N\}$ denote a catalog of primitives. We may form a robot model by selecting nonempty subset of \mathcal{RP} . A robot defined by the primitive set $R = \{P_{i_1}, \dots, P_{i_m}\} \subseteq \mathcal{RP}$ has action set $U_R = U_{i_1} \sqcup \dots \sqcup U_{i_m}$ and observation set $Y_R = Y_{i_1} \sqcup \dots \sqcup Y_{i_m}$. The \sqcup notation indicates a disjoint union operation, under which identical elements from different source sets remain distinct. The state transition function $f_R : X \times U_R \rightarrow X$, and observation function $h_R : X \times U_R \rightarrow Y_R$, are formed by unioning the f and h maps from the relevant primitives. When it can be done without ambiguity, we use the phrase *robot model* to refer directly to the set of primitives, rather than to the 5-tuple (X, U, Y, f, h) formed by these primitives. With this usage, it is meaningful to apply set operations such as union or intersection directly to robots.

Note that, given a catalog of primitives \mathcal{RP} , we can form a “master” robot model \hat{R} that includes every primitive in \mathcal{RP} . The history I-space of \hat{R} contains as a subset the history I-space of every other robot model that can be formed from \mathcal{RP} . As a result, any I-map for \hat{R} can also be used as an I-map for any robot model formed from \mathcal{RP} .

We now give several examples to illustrate the intuition of Definition 2. Examples 3-7 apply to a point robot with orientation in a bounded planar environment E , so $X = E \times S^1$. Illustrations of these primitives appear in Figures 3-5. We revisit these examples in Sections 6 and 7.

Example 2 Let $P_A = (S^1, \{0\}, f_A, h_A)$. Let f_A compute relative rotations, so that from a state $x = (x_1, x_2, \theta)$, we have $f_A(x, u) = (x_1, x_2, \theta + u)$. Since $Y_A = \{0\}$ contains only a dummy element, h_A is a trivial function always returning 0. This primitive can be implemented with an angular odometer on a mobile robot capable of rotating in place. ◊

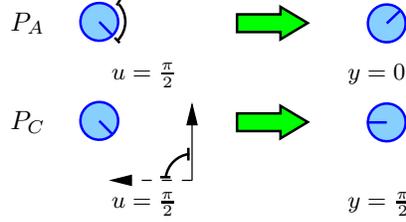

Figure 3: Sample executions of the primitives of Examples 2 and 3. [top] P_A allows the robot rotate relative to its current orientation. [bottom] P_C allows the robot to rotate relative to a globally defined “north” direction.

Example 3 Let $P_C = (S^1 \sqcup \{0\}, S^1, f_C, h_C)$. Define $f_C(x, u)$ to set the rotation coordinate of x to equal u if $u \in S^1$ or to leave x unchanged if $u \in \{0\}$. The observation function h_C returns the robot’s final orientation. This primitive amounts to allowing the robot to orient itself with respect to a global reference frame, or to sense its current orientation without rotating. One might implement this primitive using a compass on a robot that can rotate in place. \diamond

Example 4 Let $P_T = (\{0\}, \{0\}, f_T, h_T)$. Define f_T to compute a forward translation to the obstacle boundary. This primitive can be implemented with a contact sensor on a mobile robot that can reliably move forward. \diamond

Example 5 Let $P_L = ([0, \infty), [0, \infty), f_L, h_L)$. For $x \in X$ and $u \in U$, define $f_L(x, u)$ to compute a forward translation of distance at most u , stopping short only if the robot reaches an obstacle first. The observation $h_L(x, u)$ is the actual distance traveled. This primitive can be implemented with a linear odometer on a robot that can move forward reliably. Depending on implementation issues, a contact sensor may also be needed. \diamond

Example 6 Let $P_R = (\{0\}, [0, \infty), f_R, h_R)$. For all $x \in X$, $f_R(x, 0) = x$, so that this primitive never changes the robot’s state. The observation $h_R(x, u)$ is the distance to the nearest obstacle directly in front of the robot. This primitive models the capabilities of a forward-facing unidirectional range sensor. \diamond

Example 7 Let $P_G = (\{0\}, \mathbb{R}^2, f_G, h_G)$. Again, $f_G(x, u) = x$ for all x and u . For a state $x = (x_1, x_2, \theta)$, let $h_G(x, 0) = (x_1, x_2)$. This primitive roughly corresponds to a GPS device that the robot can periodically poll to determine its location in the plane. \diamond

Other possibilities for primitives include landmark detectors, wall followers, visibility sensors, and so on. A more complete listing of sensors suitable for adaptation into robotic primitives appears in Section 11.5.1 of LaValle’s book [2006].

There are several benefits to modeling robot systems as collections of primitives. First, we claim that robotic primitives represent the right level of abstraction at which *planning* problems are interesting but manageable. If we consider sensors at too fine a level of detail, the problem takes on the character of a closed-loop control system. If the primitives are too sophisticated, we risk trivializing the planning problem while creating an unbearable modeling burden. Second, by dividing time into discrete stages, we avoid the technical difficulties of describing the robot’s progression through \mathcal{I} in continuous time. This consideration is increasingly important if we allow noise to affect state transitions or observations. We address issues related to the modeling of time more completely in Section 8.3.

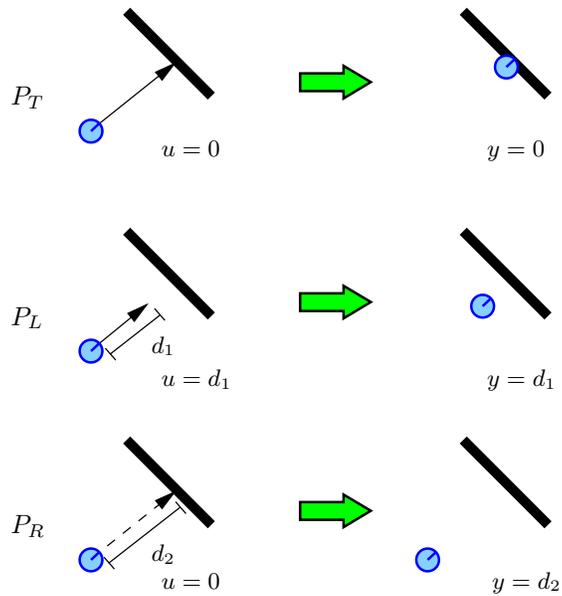

Figure 4: Sample executions of the primitives of Examples 4-6. [top] P_T allows the robot to translate forward until it reaches an obstacle. [middle] P_L allows a robot to specify a distance to translate. [bottom] P_R allows the robot to measure the distance forward to the nearest obstacle, but does not change the robot's state.

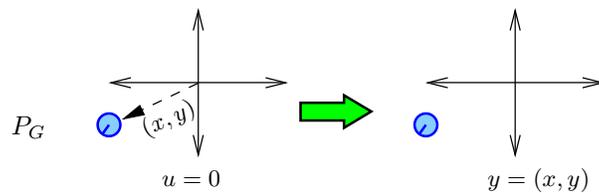

Figure 5: A sample execution of the primitive of Example 7. The robot senses its position, but its state does not change.

5 The information preference relation

Our goal is a dominance relation under which we can declare one robot “better than” another. To do so, we need a formal notion of one I-state being superior, in the sense of encoding better information, than another. To that end, choose a derived I-space \mathcal{I} and an I-map κ into \mathcal{I} . Equip \mathcal{I} with a partial order, which we call an *information preference relation*. Write $\kappa(\eta_1) \preceq \kappa(\eta_2)$ to indicate that $\kappa(\eta_2)$ is preferred to $\kappa(\eta_1)$. We require that for any $\eta_1, \eta_2 \in \mathcal{I}_{hist}$, and for any $u \in U$ and $y \in Y$,

$$\kappa(\eta_1) \preceq \kappa(\eta_2) \implies \kappa(\eta_1, u, y) \preceq \kappa(\eta_2, u, y). \quad (10)$$

This is a consistency property requiring preference for one I-state over another to be preserved across transitions in I-space.

Example 8 *Regardless of \mathcal{I} or κ , it is well-defined (but perhaps unhelpful) to use a trivial relation under which $\kappa(\eta_1) \preceq \kappa(\eta_2)$ if and only if $\kappa(\eta_1) = \kappa(\eta_2)$.* \diamond

Example 9 *Under nondeterministic uncertainty, we can define $\kappa_{ndet}(\eta_1) \preceq \kappa_{ndet}(\eta_2)$ if and only if $\kappa_{ndet}(\eta_2) \subseteq \kappa_{ndet}(\eta_1)$. To show that (10) is satisfied, suppose $\kappa_{ndet}(\eta_1) \preceq \kappa_{ndet}(\eta_2)$. Let $x \in \kappa_{ndet}(\eta_2, u, y)$. The definition of κ_{ndet} ensures that there exists some $x' \in \kappa_{ndet}(\eta_2)$ such that $f(x', u) = x$ and $h(x', u) = y$. However, because $\kappa_{ndet}(\eta_2) \subseteq \kappa_{ndet}(\eta_1)$, we have $x' \in \kappa_{ndet}(\eta_1)$. It follows that $x \in \kappa_{ndet}(\eta_1, u, y)$.* \diamond

The information preference relation we choose affects the goal regions that are sensible to consider. We should select a region in which, for every I-state in the region, we also include any I-states preferable to it. This formalizes the intuition that a robot in the goal region should not prefer to be outside the goal. Definition 3 codifies this idea of a sensible goal region.

Definition 3 *Consider a set $I \subset \mathcal{I}$ of derived I-states. If, for any $\kappa(\eta_1) \in I$ and $\kappa(\eta_2) \in \mathcal{I}$ with $\kappa(\eta_1) \preceq \kappa(\eta_2)$, we have $\kappa(\eta_2) \in I$, then I is preference closed.* \circ

Alternatively, one can view preference closure as a constraint on \preceq . Fixing a space \mathcal{G} of potential goal regions, we admit a partial order \preceq only if every region in \mathcal{G} is preference closed under \preceq . Note that the trivial definition of \preceq in Example 8 always passes this test, regardless of \mathcal{G} .

6 A dominance relation over robot systems

Now we turn our attention to a definition of dominance of one robot system over another. This dominance relation induces a partial order over robot systems, according to their sensing and actuation abilities. The intuition is that dominance is based on one robot’s ability to “simulate” another.

Definition 4 [*Robot dominance*] *Consider two robots $R_1 = (X^{(1)}, U^{(1)}, Y^{(1)}, f^{(1)}, h^{(1)})$ and $R_2 = (X^{(2)}, U^{(2)}, Y^{(2)}, f^{(2)}, h^{(2)})$. Choose a derived I-space \mathcal{I} and I-maps $\kappa^{(1)} : \mathcal{I}_{hist}^{(1)} \rightarrow \mathcal{I}$ and $\kappa^{(2)} : \mathcal{I}_{hist}^{(2)} \rightarrow \mathcal{I}$. If, for all*

- $\eta_1 \in \mathcal{I}_{hist}^{(1)}$,
- $\eta_2 \in \mathcal{I}_{hist}^{(2)}$ for which $\kappa^{(1)}(\eta_1) \preceq \kappa^{(2)}(\eta_2)$, and all
- $u_1 \in U^{(1)}$,

there exists a policy $\pi_2 : \mathcal{I}_{hist}^{(2)} \rightarrow U^{(2)}$ such that for all $x_1 \in X^{(1)}$ consistent with η_1 and all $x_2 \in X^{(2)}$ consistent with η_2 , there exists a positive integer l such that

$$\kappa^{(1)}(\eta_1, u_1, h^{(1)}(x_1, u_1)) \preceq \kappa^{(2)}(F^l(\eta_2, \pi_2, x_2)), \quad (11)$$

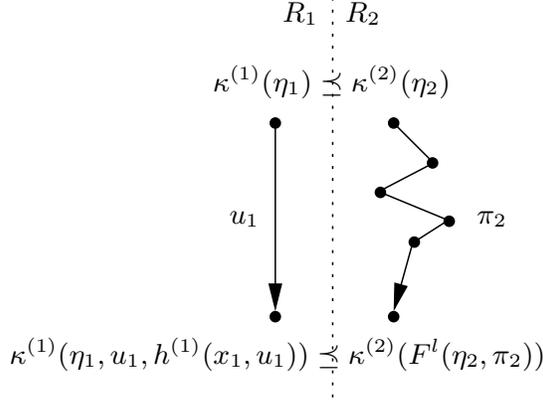

Figure 6: An illustration of Definition 4. If R_2 can always reach an I-state better than the one reached by R_1 , then $R_1 \trianglelefteq R_2$.

then R_2 dominates R_1 under $\kappa^{(1)}$ and $\kappa^{(2)}$, denoted $R_1 \trianglelefteq R_2$. If $R_1 \trianglelefteq R_2$ and $R_2 \trianglelefteq R_1$, then R_1 and R_2 are equivalent, denoted $R_1 \equiv R_2$. If $R_1 \not\trianglelefteq R_2$ and $R_2 \not\trianglelefteq R_1$ then R_1 and R_2 are incomparable, denoted $R_1 \boxtimes R_2$. \circ

Informally, Definition 4 means that, for any transition made by R_1 , there exists some strategy for R_2 to reach an information state at least as good, in the sense of information preference, as that reached by R_1 . This is what we mean when we describe the statement $R_1 \trianglelefteq R_2$ as meaning that R_2 can simulate R_1 . See Figure 6.

6.1 Dominance examples

Several examples will clarify the definition.

Example 10 Let $R_1 = \{P_R\}$ and $R_2 = \{P_A, P_L\}$. Recall the definitions of these primitives from Examples 3, 5, and 6. We argue under nondeterministic uncertainty that $R_1 \trianglelefteq R_2$ by showing that R_2 can simulate R_1 in the precise sense of Definition 4. Let $\eta_1 \in \mathcal{I}_{hist}^{(1)}$ and $\eta_2 \in \mathcal{I}_{hist}^{(2)}$ with $\kappa_{ndet}(\eta_1) \preceq \kappa_{ndet}(\eta_2)$. Since $U^{(1)} = \{0\}$, there is only one choice for u_1 . Let $l = 4$ and define π_2 so that R_2 , starting from η_2 , executes these actions in succession:

- (1) Use P_L with a very large input to move forward to the nearest obstacle. Let $d = h(x, u)$ denote the distance moved.
- (2) Use P_A with $u = 180^\circ$ to perform a half turn.
- (3) Use P_L with $u = d$ to return the robot to its initial position.
- (4) Use P_A with $u = 180^\circ$ to perform a half turn, returning the robot to its original orientation.

This policy is illustrated in Figure 7. It is easy to verify that from any $x \in X$, we have

$$\kappa_{ndet}(\eta_1, u_1, h(x, u_1)) \preceq \kappa_{ndet}(F^4(\eta_2, \pi_2, x)),$$

and therefore $R_1 \trianglelefteq R_2$. Since R_1 , which is completely immobile, cannot simulate the translations or rotations of R_2 , we have $R_2 \not\trianglelefteq R_1$.

Note that these relationships are based on the robots' ability to move through \mathcal{I}_{ndet} , and do not consider any notion of the cost of motion or sensing. The introduction of such a cost function would likely lead to Pareto optima that express tradeoffs between the complexity of sensing built into the robot and the execution costs of particular plans executed by the robot. We do not consider such tradeoffs here. \diamond

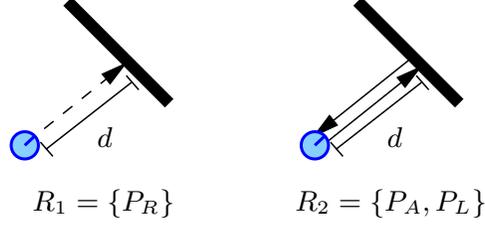

Figure 7: An illustration of Example 10. The robot $R_2 = \{P_A, P_L\}$ dominates the robot $R_1 = \{P_R\}$ because the former can simulate the latter. [left] A distance measurement made directly by R_1 . [right] Distance is measured indirectly by R_2 using its linear odometer.

Example 11 Let $R_1 = \{P_T\}$ and $R_2 = \{P_L\}$. We show under nondeterministic uncertainty that $R_1 \trianglelefteq R_2$. Let $\eta_1 \in \mathcal{I}_{hist}^{(1)}$ and $\eta_2 \in \mathcal{I}_{hist}^{(2)}$ with $\kappa(\eta_1) \preceq \kappa(\eta_2)$. There is only one choice for u_1 . Choose $l = 1$ and define π_2 to choose an input for P_L larger than the diameter of the environment. This causes the motions of R_1 and R_2 to be identical. The resulting derived I-states $\kappa(\eta'_1)$ and $\kappa(\eta'_2)$ for R_1 and R_2 are the same, except that R_2 receives a meaningful sensor reading that may reduce the resulting nondeterministic I-state. This sensor information only makes $\kappa(\eta'_2)$ smaller, so the preference $\kappa(\eta'_1) \preceq \kappa(\eta'_2)$ is maintained. Conclude that $R_1 \trianglelefteq R_2$. \diamond

It bears emphasis that the relation induced by Definition 4 depends on the I-maps used. The next two examples illustrate this.

Example 12 Let $R_1 = \{P_A\}$ and $R_2 = \{P_C\}$. We argue that $R_1 \trianglelefteq R_2$ under the usual nondeterministic I-map with the initial condition of total uncertainty. Let $\eta_1 \in \mathcal{I}_{hist}^{(1)}$ and $\eta_2 \in \mathcal{I}_{hist}^{(2)}$ with $\kappa_{ndet}(\eta_1) \preceq \kappa_{ndet}(\eta_2)$. Let $u_1 \in U_1 = S^1$. Choose $l = 2$ and define π_2 to select the following two actions:

- (1) Use P_C with $u = 0$ to sense the robot's orientation without changing the state. Let θ denote this orientation.
- (2) Use P_C to rotate the robot to orientation $\theta + u$ in the global frame.

As in Example 11, the resulting states for R_1 and R_2 are identical but, since R_2 knows its orientation, it may be able to eliminate some candidate states that R_1 cannot. This establishes that $R_1 \trianglelefteq R_2$. Are R_1 and R_2 equivalent under this I-map? No, because R_2 can, with a single action, sense its orientation, but this information can never be gathered by R_1 . Therefore $R_2 \not\trianglelefteq R_1$ and $R_1 \not\equiv R_2$. \diamond

Example 13 Consider a situation identical to that of Example 12, but modify κ_{ndet} for a different initial condition $\kappa_{ndet}(\cdot) = \mathbb{R}^2 \times \{\pi/2\}$. That is, the robot begins its execution knowing its initial orientation. At every step, R_1 knows its orientation in the global frame, and can simulate R_2 using angle addition. Therefore we have $R_2 \trianglelefteq R_1$. But using the same reasoning as in Example 12, we know $R_1 \trianglelefteq R_2$. Therefore, for this I-map, we have $R_1 \equiv R_2$. \diamond

6.2 Properties of the dominance relation

We conclude this section with some basic properties that follow from Definition 4.

Lemma 1 The dominance relation \trianglelefteq is a partial order. Likewise \equiv is indeed an equivalence relation.

Lemma 2 Consider three robots R_1 , R_2 , and R_3 formed from primitives in \mathcal{RP} and an I-map κ for the master robot model \hat{R} of \mathcal{RP} . If $R_1 \trianglelefteq R_2$ under κ , we have:

- (a) $R_1 \trianglelefteq R_1 \cup R_3$ (Adding primitives never hurts)
- (b) $R_2 \equiv R_2 \cup R_1$ (Redundancy doesn't help)
- (c) $R_1 \cup R_3 \trianglelefteq R_2 \cup R_3$ (No unexpected interactions)

Proof:

(a) Let $\eta_1 \in \mathcal{I}_{hist}^{(1)}$, $\eta_{13} \in \mathcal{I}_{hist}^{(13)}$, and $u_1 \in U_1$. Assume $\kappa(\eta_1) \preceq \kappa(\eta_{13})$. Choose $l = 1$ and $\pi_{13}(\eta) = u_1$ for all η . For all x , we have $\kappa(\eta_1, u_1, h(x, u_1)) \preceq \kappa(\eta_{13}, u_1, h(x, u_1)) = \kappa(F^l(\eta_{13}, \pi_{13}, x))$, completing the proof.

(b) It follows from part (a) that $R_2 \trianglelefteq R_1 \cup R_2$. It remains to show that $R_1 \cup R_2 \trianglelefteq R_2$. Let $\eta_{12} \in \mathcal{I}_{hist}^{(12)}$, $\eta_2 \in \mathcal{I}_{hist}^{(2)}$, and $u_{12} \in U_2 \cup U_1$. Assume $\kappa(\eta_{12}) \preceq \kappa(\eta_2)$. Either $u_{12} \in U_1$ or $u_{12} \in U_2$. If $u_{12} \in U_1$, then because $R_1 \trianglelefteq R_2$ there exist π_2 and l satisfying the definition for $R_1 \cup R_2 \trianglelefteq R_2$. If $u_{12} \in U_2$, choose $l = 1$ and $\pi_2(\eta) = u_{12}$ for all η . For all x , we have $\kappa(\eta_{12}, u_{12}, h(x, u_{12})) \preceq \kappa(\eta_2, u_{12}, h(x, u_{12})) = \kappa(F^l(\eta_2, \pi_2, x))$, completing the proof.

(c) Let $\eta_{13} \in \mathcal{I}_{hist}^{(13)}$, $\eta_{23} \in \mathcal{I}_{hist}^{(23)}$, and $u_{13} \in U_1 \sqcup U_3$. Assume $\kappa(\eta_{13}) \preceq \kappa(\eta_{23})$. Either $u_{13} \in U_1$ or $u_{13} \in U_3$. If $u_{13} \in U_1$, then because $R_1 \trianglelefteq R_2$ there exist π_{23} and l satisfying the definition for $R_1 \cup R_3 \trianglelefteq R_2 \cup R_3$. If $u_{13} \in U_3$, then choose $l = 1$ and $\pi_{23}(\eta) = u_{13}$ for all η . For all x , we have $\kappa(\eta_{13}, u_{13}, h(x, u_{13})) \preceq \kappa(\eta_{23}, u_{13}, h(x, u_{13})) = \kappa(F^l(\eta_{23}, \pi_{23}, x))$, completing the proof. \square

Corollary 3 *If $R_1 \equiv R_2$, then $R_1 \cup R_3 \equiv R_2 \cup R_3$.*

Proof: Apply Lemma 2c twice. \square

Lemma 2c might be misleading. Certainly, hardware components can be made to interact in interesting ways. For example, a control system might combine information from linear and angular odometers to execute circular arc motions. This apparent contradiction results from the definition of robotic primitives, which execute *serially*, rather than in parallel. In this sense, robotic primitives model sensing and actuation strategies as complete “packages,” rather than the individual sensors or motors themselves.

Lastly, we connect the idea of dominance to the ability of robots to complete tasks.

Lemma 4 (Solution by imitation) *Consider two robots R_1 and R_2 with $R_1 \trianglelefteq R_2$ and a preference-closed goal region \mathcal{I}_G . If R_1 can reach \mathcal{I}_G then R_2 can reach \mathcal{I}_G .*

Proof: Use the policy π_2 implied by Definition 4 to complete the task with R_2 . \square

This tight connection between dominance and task-completing ability provides some motivation for the form of dominance we propose.

7 Extended example: Global localization

In this section we present a detailed example using the definitions of Sections 5 and 6. We consider a *global localization* task, in which the robot has an accurate map of its environment but has no knowledge of its position within that environment. Many forms of the localization problem with varying sensing modalities have been studied in great detail. Some methods [Avis and Imai, 1990, Basye and Dean, 1990, Cox, 1991, Dellaert et al., 1999, Demaine et al., 2002, Guibas et al., 1995, Sugihara, 1988, Ladd et al., 2004, Weiss et al., 1994] passively observe the motions of the robot in order to draw conclusions about the robot’s state. Others [Dudek et al., 1998, Kleinberg, 1994, Koenig et al., 2006, O’Kane and LaValle, 2007b, Rao et al., 2004, Romanik and Schuierer, 1996] actively drive the robot to reduce uncertainty. The purpose of this example is to show how the results of Section 6 can be used to discover the information requirements of this particular problem in robotics. An analogy can be made to the classification of languages in the theory of computation. It has been shown, for example, that to accept the language of palindromes requires a machine with computation abilities at least as powerful as a pushdown automaton. In this section, we derive similar results regarding the sensing and motion abilities needed to complete the active global localization task.

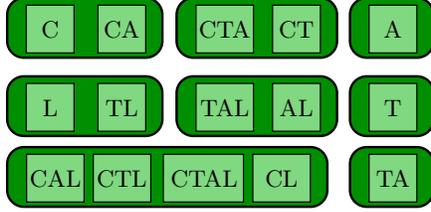

Figure 8: Fifteen robot models grouped into their eight equivalence classes.

7.1 Task definition

Let $E \subseteq \mathbb{R}^2$ denote a planar environment in which a point robot moves. Assume that E is polygonal, bounded, closed, and simply-connected and that the rotational symmetry group of E is trivial. As in previous examples, the robot's state space is $X = E \times S^1$. We consider a catalog $\mathcal{RP} = \{P_A, P_C, P_T, P_L\}$ of four primitives from Examples 2-4. From these primitives we can form 15 distinct robots. For brevity, we use concatenation to indicate the primitives with which a robot is equipped, so that CT refers to a robot with primitive set $\{P_C, P_T\}$; similar names apply to the other 14 robot models.

Select $\mathcal{I} = \text{pow}(X) - \emptyset$. For κ , use the nondeterministic map defined in Example 1. The initial condition is total uncertainty, so $\kappa(\cdot) = X$. For the information preference relation, use the definition from Example 9, in which information preference is defined by subset containment. The goal region for the localization task is

$$\mathcal{I}_G = \{\eta \in \mathcal{I} \mid |\eta| = 1\}. \quad (12)$$

That is, we want to command the robot so that only a single final state is consistent with its history I-state. If the robot can complete the task for any E consistent with the assumptions above, we say that the robot can localize itself.

7.2 Equivalences and dominances

Although \mathcal{RP} generates 15 robot models, we can use the results of Section 6 to group them into equivalence classes.

Lemma 5 *The following equivalences hold:*

- (a) $CA \equiv C$
- (b) $CTA \equiv CT$
- (c) $TL \equiv L$
- (d) $TAL \equiv AL$
- (e) $CAL \equiv CTL \equiv CTAL \equiv CL$

The three remaining robot models, A, T, and AT, are in singleton equivalence classes.

Proof: (a) Combine Example 12 and Lemma 2b. (b) Combine Example 12, Lemma 2b, and Corollary 3. (c) Combine Example 11 and Lemma 2b. (d) Combine Example 11, Lemma 2b, and Corollary 3. (e) Combine Examples 11 and 12, Lemma 2b, and Corollary 3. \square

These equivalences are illustrated in Figure 8. From each, select the unique robot with the fewest primitives and discard the remaining 7 robots. We can state several dominances between these classes.

Lemma 6 *Between representatives of the equivalence classes from Lemma 5, the following dominances hold:*

- (a) $C \trianglelefteq CT \trianglelefteq CL$

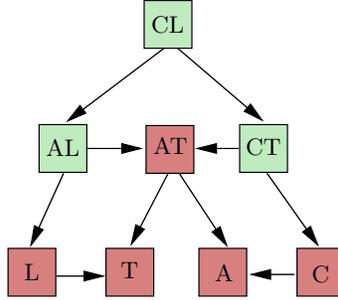

Figure 9: Classification of robot models under which the localization task can be completed. Shaded models do not admit a solution. Arrows indicate dominances.

(b) $A \trianglelefteq AT \trianglelefteq AL \trianglelefteq CL$

(c) $L \trianglelefteq AL \trianglelefteq CL$

(d) $T \trianglelefteq AT \trianglelefteq CT \trianglelefteq CL$

Proof: Combine Examples 11 and 12 with Lemma 2a. □

7.3 Completing the localization task

Which equivalence classes contain robots that can complete the localization task? First, notice that some robot models are so simple that we can rule them out immediately.

Lemma 7 *None of C, A, L, and T can localize themselves.*

Proof: For C and A, notice that no action changes the robot’s position and no observation is influenced by position. Therefore neither robot can ever gather information about its position. For L and T, notice that the robot can never change its orientation. Information available to the robot is limited to the ray extending from its initial state to the nearest obstacle forward. Since E may contain continua of starting states consistent with this information, neither robot can localize itself. □

Prior results are helpful for the remaining cases.

Lemma 8 (O’Kane and LaValle [2007b]) *AL and CT can localize themselves but AT cannot.*

Finally, we can finish the classification. The results of Lemmas 7-9 are summarized in Figure 9.

Lemma 9 *CL can localize itself.*

Proof: Combine Lemma 4 with Lemma 8. □

The result is a complete classification of the solvability of the localization problem over this hierarchy.

8 Extensions and generalizations

This section contains a series of extensions and generalizations to the techniques presented in Sections 3-6. The intention is to illustrate that, although the preceding results are for a class of highly idealized systems, the general structure of our analysis is useful for a wider variety of problems with greater degrees of realism and generality. We propose methods for dealing with unknown environments (Section 8.1), with sensing and control uncertainty (Section 8.2), and with continuous time (Section 8.3). Although we present each method separately, the extensions are orthogonal in the sense that it is straightforward to apply all of them at once.

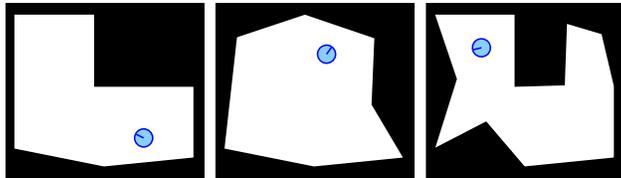

Figure 10: Three states for an example system containing a mobile robot in the plane with environment uncertainty. When the environment is uncertain, the identity of the environment becomes part of the state of the system.

8.1 Unknown environments

In the preceding analysis, we assumed that the robot moves in a fixed, known environment. What happens when the robot begins with limited or no knowledge about its environment, in the sense that positions and geometry of obstacles, map topology, navigability of terrain, and so on are unknown? Imperfect knowledge about the environment is a more drastic instance of the general issue of state uncertainty. If the state is defined to include a description of the environment in addition to the robot’s configuration, then uncertainty in the environment can be represented as an additional dimension of state uncertainty.

Concretely, choose an *environment space* \mathcal{E} of which each element $E \in \mathcal{E}$ is a potential environment for the robot. Possibilities for \mathcal{E} with varying degrees of realism, interest, practicality, and amenability to analysis, include:

1. the set of bounded planar grids with occupancy maps,
2. the set of simple polygons in the plane, and
3. the set of compact regions in \mathbb{R}^2 or \mathbb{R}^3 with connected interiors and piecewise analytic boundaries.
4. the set of terrain maps from \mathbb{R}^2 to \mathbb{R} , giving the elevation or navigability at each point in the plane.

The state space is formed by combining the robot’s configuration space \mathcal{C} with \mathcal{E} , so that $X = \mathcal{C} \times \mathcal{E}$. See Figure 10. In the complete model, the true environment $E \in \mathcal{E}$ affects the robot by influencing the state transitions that the robot makes and the observations that the robot receives. Since the only change is to use a more complicated state space, Definition 4 need not change, and the results of Section 6 still hold.

8.2 Imperfect sensing and control

We have assumed so far that the robot can execute all of its actions with perfect precision and complete reliability. The motions of real robots are imprecise and unpredictable. Moreover, although we have accounted for the importance of sensing by assuming that the robot is uncertain of its current state and must rely on sensing, we have assumed that sensor readings are uncorrupted by noise. A more realistic sensor model would allow information from sensors to be subject to error.

We propose to follow the approach used in game theory [Papadimitriou, 1985, Blackwell and Girshik, 1979] and represent this uncertainty by envisioning an abstract external decision maker called “nature.” The current state, the action chosen by the robot, and the choices made by nature combine to determine how the state changes; given this information, the state trajectory is fully determined. See Figure 11. Formally, define a *nature action space* Θ and augment the state transition function f to depend on nature’s choice of $\theta \in \Theta$ at each stage, so that $f : X \times U \times \Theta \rightarrow X$. Nature affects the robot’s observations in a similar way. Define a *nature observation action space* Ψ and redefine the observation function $h : X \times U \times \Psi \rightarrow Y$. The policy application function F must be generalized to account for nature actions, so that

$$\eta_{m+k} = F^m(\eta_k, \pi, x_k, \theta_k, \dots, \theta_{k+m}, \psi_k, \dots, \psi_{k+m}). \quad (13)$$

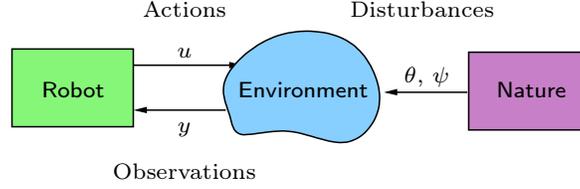

Figure 11: As the robot interacts with its environment, an artificial decision maker nature generates disturbances.

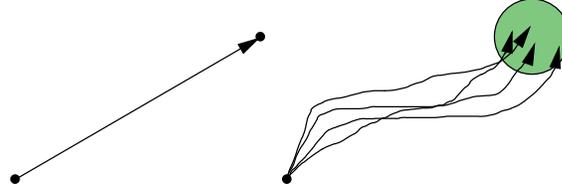

Figure 12: [left] The robot in Example 14 gives displacement inputs that determine a nominal trajectory. [right] Nature interferes with this motion, but error bounds ensure that the final state is contained in a circle of radius $k\theta_{max}$.

Note that, in contrast to the simpler formulation of Equation 6, the robot's current state, history I-state, and policy are no longer sufficient to predict future history I-states.

The next examples illustrate how nature might interfere.

Example 14 Consider a point robot that can move freely in the plane by issuing displacement commands, but whose motion is subject to noise. Let u_{max} denote a bound on the magnitude of the displacement in each stage, and let θ_{max} denote a bound on magnitude of the error in this displacement. Let $X = \mathbb{R}^2$, $U = \{u \in \mathbb{R}^2 \mid \|u\| \leq u_{max}\}$, $\Theta = \{\theta \in \mathbb{R}^2 \mid \|\theta\| \leq \theta_{max}\}$, and $f(x, u, \theta) = x + u + \theta$. At stage k , the robot can be certain that its state lies within a closed disk of radius $k\theta_{max}$, centered at the nominal (error free) final point. See Figure 12. \diamond

Example 15 Suppose a mobile robot has a sensor that reports the distance to some landmark. Let $X = \mathbb{R}^2$ and $Y = [0, \infty)$. Without loss of generality, position the landmark at the origin. Assume that the sensor has bounded additive error, so that $\Psi = [-\psi_{max}, \psi_{max}]$ and $h(x, \psi) = \|x\| + \psi$. See Figure 13. At each stage, the robot knows that its state is within an annulus of width $2\psi_{max}$, centered at the origin. \diamond

In the presence of interference from nature, there are at least two relevant solution concepts.

1. A strategy $\pi : \mathcal{I}_{hist} \rightarrow U$ is a *possible solution* if there exists some stage k and choices of $\theta_1, \dots, \theta_k$ and ψ_1, \dots, ψ_k for which the robot reaches a derived I-state $\eta_k \in \mathcal{I}_G$. The robot may reach \mathcal{I}_G , but it is also possible that control or sensing errors will prevent it from achieving this goal.
2. A strategy $\pi : \mathcal{I}_{hist} \rightarrow U$ is a *guaranteed solution* if there exists some stage k such that for all choices of $\theta_1, \dots, \theta_k$ and ψ_1, \dots, ψ_k , the robot reaches a derived I-state $\eta_k \in \mathcal{I}_G$. The robot can always reach its goal, regardless of any interference by nature.

Other solution concepts, such as those based on performance bounds or on probabilistic guarantees of reaching the goal, are possible but we do not consider them here. In this context, Definition 4 must be generalized to include universal quantifiers over nature's actions.

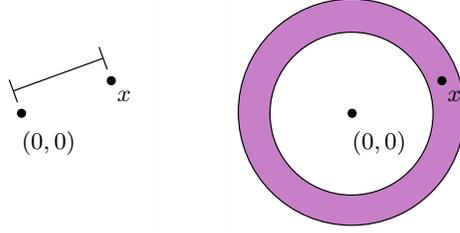

Figure 13: [left] The robot in Example 15 has a sensor that reports a noisy estimate of the distance to the origin. [right] Accounting for noise bounded by ψ_{max} , the observation confines the robot's state to an annulus of width $2\psi_{max}$.

Definition 5 [*Robot dominance with sensing and control error*] Consider two robot systems $R_1 = (X^{(1)}, U^{(1)}, Y^{(1)}, \Theta^{(1)}, \Psi^{(1)}, f^{(1)}, h^{(1)})$ and $R_2 = (X^{(2)}, U^{(2)}, Y^{(2)}, \Theta^{(2)}, \Psi^{(2)}, f^{(2)}, h^{(2)})$. Choose a derived I-space \mathcal{I} and I-maps $\kappa^{(1)} : X^{(1)} \rightarrow \mathcal{I}$ and $\kappa^{(2)} : X^{(2)} \rightarrow \mathcal{I}$. If, for all

- $\eta_1 \in \mathcal{I}_{hist}^{(1)}$,
- $\eta_2 \in \mathcal{I}_{hist}^{(2)}$ for which $\kappa^{(1)}(\eta_1) \preceq \kappa^{(2)}(\eta_2)$, and all
- $u_1 \in U^{(1)}$,

there exists a policy $\pi_2 : \mathcal{I}_{hist}^{(2)} \rightarrow U^{(2)}$ such that for all $x_1 \in X^{(1)}$ consistent with η_1 and all $x_2 \in X^{(2)}$ consistent with η_2 , there exists a positive integer l such that for all

- $\theta_1 \in \Theta^{(1)}$,
- $\psi_1 \in \Psi^{(1)}$,
- $\theta_{2,1}, \dots, \theta_{2,l} \in \Theta^{(2)}$,
- $\psi_{2,1}, \dots, \psi_{2,l} \in \Psi^{(2)}$,

we have

$$\kappa^{(1)}(\eta_1, u_1, h^{(1)}(x_1, u_1, \psi_1)) \preceq \kappa^{(2)}(F^l(\eta_2, \pi_2, x_2, \theta_{2,1}, \dots, \theta_{2,l}, \psi_{2,1}, \dots, \psi_{2,l})) \quad (14)$$

then R_2 dominates R_1 under $\kappa^{(1)}$ and $\kappa^{(2)}$, denoted $R_1 \preceq R_2$. ◦

The next example demonstrates that Definition 5 behaves reasonably.

Example 16 (Varying error bounds) Recall the incompletely specified models in Examples 14 and 15. Consider two robot systems R_1 and R_2 with state transitions as in Example 14 and observations as in Example 15; R_1 and R_2 differ only in their error bounds $\theta_{max}^{(1)}$, $\psi_{max}^{(1)}$, $\theta_{max}^{(2)}$, and $\psi_{max}^{(2)}$. We compare these robots under κ_{ndet} . Comparing $\theta_{max}^{(1)}$ to $\theta_{max}^{(2)}$, and $\psi_{max}^{(1)}$ to $\psi_{max}^{(2)}$, there are four cases:

1. If $\theta_{max}^{(1)} = \theta_{max}^{(2)}$ and $\psi_{max}^{(1)} = \psi_{max}^{(2)}$, then $R_1 \equiv R_2$.
2. If $\theta_{max}^{(1)} \leq \theta_{max}^{(2)}$ and $\psi_{max}^{(1)} \leq \psi_{max}^{(2)}$, then $R_2 \preceq R_1$.
3. If $\theta_{max}^{(2)} \leq \theta_{max}^{(1)}$ and $\psi_{max}^{(2)} \leq \psi_{max}^{(1)}$, then $R_1 \preceq R_2$.
4. Otherwise, $R_2 \boxtimes R_1$.

These results follow in a straightforward manner from Definition 5. The intuition is that one robot system dominates the other if and only if its error bounds are not larger. ◊

8.3 Continuous time

The models presented to this point manage time in discrete stages, in which the robot makes a single decision at each stage. This discretization of time may be unsatisfactory for many kinds of systems, especially those that require complicated control strategies. Continuous-time models have a more direct correspondence with reality. To make the appropriate generalizations, we replace the discrete sequences of states, actions, and observations with functions of a continuous time parameter t .

The state space X , action space U , and observation space Y remain unchanged from the discrete stage formulation. At each instant t , the robot chooses some $u(t) \in U$. Let \tilde{U}_t denote the space of all functions from $[0, t)$ into U , and let $\tilde{U} = \bigcup_{t \in [0, \infty)} \tilde{U}_t$. For simplicity of notation, adopt the convention that $[0, 0) = \emptyset$. Define $\tilde{u} : [0, \infty) \rightarrow U$ as the robot's complete action history, and let $\tilde{u}_t \in \tilde{U}$ denote the robot's action history up to (but exclusive of) time t . We include a special *termination action* $u_T \in U$. The robot selects u_T to indicate that it has finished its task and intends to terminate execution. We require that if $u(t) = u_T$, then $u(t') = u_T$ for all $t' > t$. We describe changes in the state with a *state transition function*

$$\Phi : X \times \bigcup_{t \in [0, \infty)} \tilde{U}_t \rightarrow X. \quad (15)$$

The intuition is that, given a starting state $x(0)$, and an action history \tilde{u}_t , the state transition function computes the resulting state

$$x(t) = \Phi(x(0), \tilde{u}_t). \quad (16)$$

This notation of a “black box” state transition function follows notation employed in control theory, for example by Chen [1984].

Example 17 *A familiar special case of (16) occurs if \tilde{u} is a smooth function and there exists a function f such that*

$$\Phi(x(0), \tilde{u}_t) = x(0) + \int_0^t f(x(s), u(s)) ds. \quad (17)$$

In this case, the system dynamics can be described by the differential equation $\dot{x} = f(x, u)$. \diamond

As time passes, the robot's sensors provide feedback in the form of observations drawn from an observation space Y . Let \tilde{Y}_t denote the space of functions mapping $[0, t]$ into Y and let $\tilde{Y} = \bigcup_{t \in [0, \infty)} \tilde{Y}_t$. The robot's complete observation history is $\tilde{y} : [0, \infty) \rightarrow Y$. The observation history up to t (inclusive) is $\tilde{y}_t \in \tilde{Y}_t$. The observations received by the robot are governed by the observation function¹ $h : X \rightarrow Y$. The history I-state becomes

$$\mathcal{I}_{hist} = \bigcup_{t \in [0, \infty)} \tilde{U}_t \times \tilde{Y}_t, \quad (18)$$

and the history I-state at time t is $\eta(t) = (\tilde{u}_t, \tilde{y}_t) \in \mathcal{I}_{hist}$. A state x is consistent with an I-state $\eta(t) = (\tilde{u}_t, \tilde{y}_t)$ if and only if there exists some starting state $x(0)$ such that $\Phi(x(0), \tilde{u}_t) = x$ and $h(x(t')) = y(t')$ for $t' < t$.

We describe the robot's strategy as a feedback policy $\pi : \mathcal{I}_{hist} \rightarrow U$ that specifies an action for each history I-state. We assume that a given strategy is executed until it selects u_T . The time when this occurs, the resulting final state, and the observations received along the way are all affected by the strategy π itself and the starting state $x(0)$. Assuming that the robot executes π , the termination time is

$$T(\pi, x(0)) = \inf\{t \in [0, \infty) \mid \pi(\eta(t)) = u_T\}. \quad (19)$$

¹In our discrete-stage formulation, we used a slightly different observation model, in which $h : X \times U \rightarrow Y$. In a continuous-time adaptation, the time period over which observations are available is the half-open interval $[0, t)$; \tilde{y}_t would be undefined at t itself. As a result, the closest we could come to a memoryless strategy is to use the left-hand limit of \tilde{y}_t at t , $\kappa_{obs}(\eta(t)) = \lim_{t' \rightarrow t^-} y(t')$, provided the limit exists. (Compare to Example 19.) This technicality is part of the motivation for preventing y from depending directly on u , as we have done in this section. A more complete treatment of these kinds of sensor models appears in Section 11.1.1 of [LaValle, 2006].

The final state, denoted $F(\pi, x(0))$, is

$$F(\pi, x(0)) = \Phi(x(0), \tilde{u}_{T(\pi, x(0))}). \quad (20)$$

The next three examples illustrate that feedback over a derived I-space can be a natural way to express familiar kinds of strategies.

Example 18 (Open loop strategy) Let $\mathcal{I}_{time} = [0, \infty)$ and consider the I-map $\kappa_{time}(\eta(t)) = t$. In this case, the derived I-state is simply the time elapsed. If the robot has an intended open loop action trajectory $\omega : [0, t_f] \rightarrow U$, a strategy to execute γ is $\pi(\eta(t)) = \omega(\kappa_{time}(\eta(t)))$ if $t < t_f$ and $\pi(\eta(t)) = u_T$ otherwise. \diamond

Example 19 (Memoryless strategy) Another possibility is that it is enough to know the “most recent” observation, so $\mathcal{I}_{obs} = Y$ and $\kappa_{obs}(\eta(t)) = y(t)$. Given a memoryless plan $\gamma : Y \rightarrow U$, the composed function $\kappa_{obs} \circ \gamma : \mathcal{I}_{hist} \rightarrow U$ is a memoryless information feedback strategy. \diamond

Example 20 (Concatenating strategies) Given two strategies π_1 and π_2 , a new strategy that concatenates them (that is, executes them in sequence) is expressed by $\pi(\eta(t)) = \pi_1(\eta(t))$ if $\pi_1(\eta(t)) \neq u_T$ and $\pi(\eta(t)) = \pi_2(\eta(t))$ otherwise. By nesting this construction, arbitrarily many strategies can be chained together. \diamond

Definition 4 generalizes in a natural way.

Definition 6 [Robot dominance in continuous time] Consider two continuous-time robot systems $R_1 = (X^{(1)}, U^{(1)}, Y^{(1)}, \Phi^{(1)}, h^{(1)})$, and $R_2 = (X^{(2)}, U^{(2)}, Y^{(2)}, \Phi^{(2)}, h^{(2)})$. If, for all

- $\eta^{(1)}(t_1) \in \mathcal{I}_{hist}^{(1)}$,
- $\eta^{(2)}(t_2) \in \mathcal{I}_{hist}^{(2)}$ for which $\kappa^{(1)}(\eta^{(1)}(t_1)) \preceq \kappa^{(2)}(\eta^{(2)}(t_2))$,
- $t'_1 \in [0, \infty)$, and all
- $\tilde{u}_{t'_1}^{(1)} \in \tilde{U}_{t'_1}^{(1)}$,

there exists an information feedback strategy $\pi_2 : \mathcal{I}_{hist}^{(2)} \rightarrow U^{(2)}$, such that for all $x^{(1)} \in X^{(1)}$ consistent with $\eta^{(1)}(t_1)$ and $x^{(2)} \in X^{(2)}$ consistent with $\eta^{(2)}(t_2)$, there exists $t'_2 \in [0, \infty)$ such that if R_1 executes $\tilde{u}_{t'_1}^{(1)}$ from time t_1 to t'_1 and R_2 executes $\pi^{(2)}$ from time t_2 to t'_2 , we have

$$\kappa^{(1)}(\eta^{(1)}(t'_1)) \preceq \kappa^{(2)}(\eta^{(2)}(t'_2)) \quad (21)$$

then R_2 dominates R_1 under $\kappa^{(1)}$ and $\kappa^{(2)}$, denoted $R_1 \trianglelefteq R_2$. \circ

See Figure 14. The next two examples illustrate some implications of Definition 6.

Example 21 (Omniscient sensing and perfect control) Consider a degenerate case with $Y = X$, and $h(x) = x$. This situation gives the robot complete information about its state. Choose $\mathcal{I} = X$ and $\kappa(\eta(t)) = y(t) = x(t)$. Let $\kappa(\eta_1) \preceq \kappa(\eta_2)$ if and only if $\kappa(\eta_1) = \kappa(\eta_2)$, as in Example 8. In this context, Definition 4 becomes a statement about the regions of state space reachable by different control systems.

Suppose three such systems R_1 , R_2 , and R_3 differ only in their action spaces $U^{(1)}$, $U^{(2)}$, and $U^{(3)}$. Let $Z(A)$ denote the subset of state space reachable by a robot with action space A . Suppose $R_1 \trianglelefteq R_2$. R_3 need

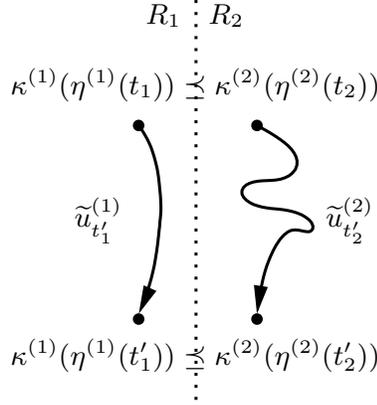

Figure 14: An illustration of Definition 6. Compare to Figure 6.

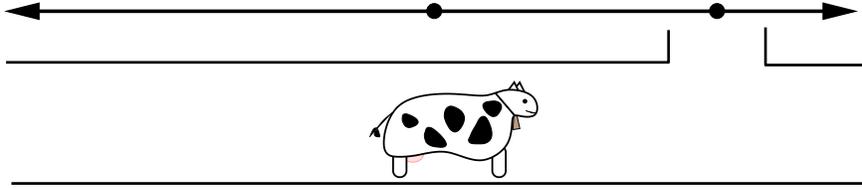

Figure 15: The lost cow of Example 22 searching for a gate.

not be comparable to either R_1 or R_2 . Note that additional robot models can be constructed from unions of $U^{(1)}$, $U^{(2)}$, and $U^{(3)}$. We have the following results:

$$Z(U^{(1)}) \subseteq Z(U^{(2)} \cup U^{(3)}) \quad (22)$$

$$Z(U^{(1)}) = Z(U^{(1)} \cup U^{(2)}) \quad (23)$$

$$Z(U^{(1)} \cup U^{(3)}) \subseteq Z(U^{(2)} \cup U^{(3)}) \quad (24)$$

These results are analogous to Lemma 2. Note that in combining action spaces in this way, we allow the robot to choose sequentially the action set from which to choose its action. The results fail if the robot is somehow allowed to choose actions from each constituent set in parallel. \diamond

Example 22 (A Lost Cow) A well-known problem in online algorithms is the lost cow problem [Kao et al., 1993, Baeza-Yates et al., 1993] in which a near-sighted cow moves along a fence searching for a gate, as illustrated in Figure 15. The difficulty under the standard sensing model is that the cow must systematically search in both directions from its initial position without any information about the distance or direction to the gate. The interest in this problem derives from potential applications in (or at least the potential for better understanding of) exploration in unbounded environments.

We formulate the lost cow problem and consider how the sensing model affects the cow's searching ability. Let $X = \mathbb{R}$, in which $x(t)$ is the position of the gate relative to the cow at time t . Let the action space be $U = [-1, 1]$ with $\Phi(x(0), \tilde{u}_t) = x(0) + \int_0^t u(s) ds$. We compare three distinct models C_1 , C_2 , and C_3 under κ_{ndet} .

1. C_1 : Let $Y^{(1)} = \mathbb{R}$ and $h^{(1)}(x) = x$. Here the cow can determine both the direction and distance to the gate.

2. C_2 : Let $Y^{(2)} = \{-1, 0, 1\}$ and $h(x) = \text{sign}(x)$. This allows the cow to determine the direction it must move to reach the gate, but not the distance.
3. C_3 : Let $Y^{(3)} = \{0, 1\}$ and $h^{(2)}(x) = 1$ if $x = 0$ and $h^{(2)}(x) = 0$ otherwise. This is the standard lost cow sensing model, in which the cow cannot see the gate from a distance, but can detect the gate when it arrives.

Perhaps surprisingly, these three models are equivalent in the sense of Definition 6. This is because each can eventually determine its state (by finding the gate) and after the state is known, state uncertainty cannot recur. To simulate C_1 with C_3 , first execute the algorithm of Baeza-Yates et al. [1993], then move to the state occupied by C_1 . \diamond

We conclude our discussion of continuous-time models by showing how a discrete stage model in the form of Section 3 can be constructed from a continuous-time model in the form presented above. Consider a division of time into variable length stages, in which, in each stage, the robot executes a single information feedback strategy to completion. We require of each of these strategies the following special property:

Definition 7 [History invariance] *If, for all $\eta(t) \in \mathcal{I}_{hist}$, all $x \in X$ consistent with $\eta(t)$, and all $y(0) \in Y$, we have $F(\pi, x, \eta(t)) = F(\pi, x, \eta(0))$, then π is a history-invariant strategy.* \circ

The intuition of the definition is that the robot executing π is free to use the observation and action history generated during its own execution, but it cannot peer into the past before its execution began in order to make decisions. Given a continuous-time robot system $R = (X, U, Y, \Phi, h)$ (as defined in this section) and a set Π of history-invariant information feedback strategies, construct a discrete-stage system (as in Section 3) $\bar{R} = (X, \bar{U}, \bar{Y}, \bar{f}, \bar{h})$ as follows:

1. The state space X is the same.
2. The action space is $\bar{U} = \Pi$.
3. The observation space is $\bar{Y} = \tilde{Y}$.
4. The state transition function is $f : X \times \bar{U} \rightarrow X$, with $f(x, \pi) = F(\pi, x, \eta(0))$.
5. The observation function is $h : X \times \bar{U} \rightarrow \bar{Y}$.

The system starts at some (unknown) initial state $x_1 \in X$. Let $x_k \in X$, $u_k \in \bar{U}$, and $y_k \in \bar{Y}$, denote the appropriate values at stage k . These sequences are related to each other by $x_{k+1} = f(x_k, u_k)$ and $y_k = h(x_k, u_k)$. The history I-state consists of the action and observation histories: $\eta_k = (u_1, y_1, \dots, u_{K-1}, y_{K-1})$. This construction gives a discrete-stage system faithful to the dynamics in both state space and I-space of the underlying continuous time system.

Lemma 10 *Any action sequence u_1, \dots, u_K executed by \bar{R} reaches the same final state x and the analogous final history I-state as does R .*

Note, however, that in making this transformation, we must choose a set Π of strategies and may therefore restrict the space of plans that the robot can execute. If Π does not contain a sufficiently rich selection of information feedback strategies, there may be regions of I-space that are no longer reachable under the discretized model. In this way, Π is analogous to the catalog of robotic primitives \mathcal{RP} introduced in Section 4.

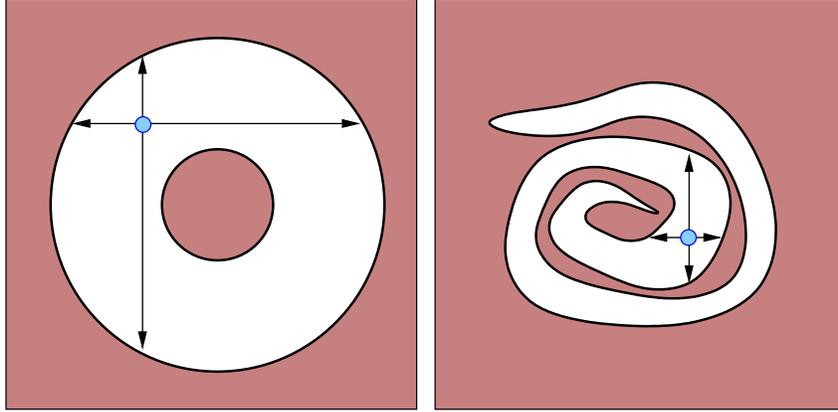

Figure 16: A sample decision problem. What sensing is required to decide if a planar environment is simply connected? What robots can distinguish the annulus environment on the left from the helix on the right?

9 Discussion

The results of this paper are intended to lay a foundation for a sensor-centered theory for comparing robotic problems and systems. Great potential exists to build on this foundation, particularly by developing the analogy to the theory of computation even further.

The most obvious avenue for future work is to study a broader collection of problems. Although this paper considers an active global localization problem in detail, other fundamental robotics problems warrant similar analysis of their information requirements. For example, results exist for limited-sensing versions of navigation [Kamon et al., 1999, Lumelsky and Tiwari, 1994, Lumelsky and Stepanov, 1987, Papadimitriou and Yannakakis, 1991], exploration [Acar and Choset, 2001b, Choset and Burdick, 1995, Ó. Dúnlaing and Yap, 1982, Tovar et al., 2004], and manipulation [Akella and Mason, 1998, Erdmann and Mason, 1988, Goldberg, 1993, Agarwal et al., 2001, Akella et al., 2000] tasks. Using the techniques we have presented, it should be possible to unify and extend these results to develop a more complete understanding of the sensing and motion abilities needed to solve these problems. Other problems and more complex sensing systems could also be investigated.

One of the most powerful ideas in the theory of computation that we have not explored here is the idea of *reductions*, which hold promise for comparing robotic problems themselves. The resulting statements would have the form “Problem A is at least as hard as Problem B.” To make things more concrete, we might consider *decision problems*, in which the robot with a state space defined as in Section 8.1 must determine if its environment $E \in \mathcal{E}$ has a certain property. Such problems can be expressed naturally as planning problems in I-space. To decide if E has a property $\Xi : \mathcal{E} \rightarrow \{0, 1\}$, the robot must reach the goal region

$$\mathcal{I}_{G,\Xi} = \{\eta \in \mathcal{I}_{hist} \mid \forall(q, E) \in \kappa_{ndet}(\eta), \Xi(E) = 1\} \cup \{\eta \in \mathcal{I}_{hist} \mid \forall(q, E) \in \kappa_{ndet}(\eta), \Xi(E) = 0\}. \quad (25)$$

An example is in Figure 16.

Another direction is to study the computational requirements of robotics problems. We expect that there exist rich tradeoffs between computation time, memory usage, sensing requirements, and solution quality. Some research has been done for certain tasks, for example exploration [Shannon, 1952, Bender et al., 1998, Blum and Kozen, 1978], pursuit-evasion [T. Kameda and Suzuki, 2006], and coverage [Wagner et al., 1999], but very little is known in general. One way to deal with such issues is to study *sufficient I-maps* [LaValle, 2006], which are I-maps for which transitions can be computed directly in the derived I-space, allowing the history to be discarded. For example, if a problem can be solved under a given robot model using a sufficient I-map into a derived I-space of finite cardinality n , the memory required to solve the problem is $O(\log n)$. The results of Blum and Kozen [1978], for example, can be characterized as showing how a discrete exploration

problem can be solved in a derived I-space with cardinality linear in the height of the area to be explored, meaning that only logarithmic memory is required. These computational issues must be approached with care, especially if those computations involve real numbers [Blum et al., 1998].

In spite of these possibilities, there are important limitations to the idealized models we presented. Of the many issues remaining to be addressed, we mention a few here.

Probabilistic uncertainty We have focused our attention on nondeterministic uncertainty, but a large subset of contemporary work in robotics uses probabilistic models of uncertainty [Austin and Jensfelt, 2000, Thrun et al., 2005, Fox et al., 1998, Jensfelt and Kristensen, 2001, Shatkay and Kaelbling, 1997, Simmons and Koenig, 1995]. Our results also apply, at least in principle, to probabilistic uncertainty. In this context, the relevant derived I-space is a space of probability distributions over X . However, it is not immediately clear what the “right” information preference relation over such a space would be. Depending on the models used, it may also be necessary to relax Definition 4 to require only that R_2 can simulate R_1 with sufficiently high probability. More generally, the differences between nondeterministic and probabilistic uncertainty models warrant further exploration. For example, nondeterministic uncertainty has the property that sensing can only help. Actions from primitives like P_R (Example 6) or P_G (Example 7) that do not change the state always lead to a derived I-state at least as good as the current one. Under probabilistic uncertainty, this property does not obviously hold, and sensing can sometimes increase uncertainty.

Selecting the catalog of primitives Although we believe that our robotic primitives provide a useful abstraction, any results derived using our methods are meaningful only if \mathcal{RP} is diverse enough to faithfully represent the underlying system. It remains an open problem to systematically find small (or at least succinctly described) sets of robotic primitives that are complete (or nearly complete) in the sense of not eliminating any reachable regions in I-space. There is, however, active interest in related problems for control systems [Frazzoli, 2001, Murphey, 2006, Mehta et al., 2006, Girard and Pappas, 2006].

What happens if \mathcal{RP} is not a finite set? For example, we may extend P_L (from Example 5) to a family $\{P_{L,\epsilon} = (S^1, \{0\}, f_{L,\epsilon}, h_{L,\epsilon}) \mid \epsilon \geq 0\}$ of primitives, each using a noisy linear odometer whose error is bounded by ϵ . If \mathcal{RP} contains many such families of primitives, and we assume each robot has at most one primitive from each family, then the space of robot models is a cube in \mathbb{R}^n . The problem of identifying the region in which a given task can be solved is correspondingly more difficult.

Efficiency and optimality Throughout this paper, we have neglected the question of the robot’s efficiency in completing its tasks. This weakness is particularly evident, for example, in Example 10, in which the statement of dominance does not consider the differences in execution cost, which in this case are likely to be prohibitively large. One established technique for taking such costs into account is to use *competitive ratios* [Gabriely and Rimon, 2004, Icking et al., 2002], which compare the execution costs of online algorithms (which must gather information during their execution) to offline methods (which have complete information) for the same tasks. It may be fruitful to generalize this notion by considering “relative competitive ratios” that bound the additional cost accrued by replacing one robot system with another dominant robot system.

Parameterization of time In Section 8.3, we parameterized the robot’s observations by time. In doing so, we implicitly assumed that the robot has an accurate clock. Although such an assumption is generally not technologically impractical, it requires care in abstract models to ensure that the robot cannot acquire extra information “for free.” A robot might, for example, use this implicit clock to parlay an accurate velocity sensor into a perfect odometer. One solution is to express \tilde{u} and \tilde{y} as functions of some other abstract parameter p . To recover the original functions of time, the robot must determine a hidden mapping from \mathbb{R} to \mathbb{R} under which p maps to t . Such issues are addressed in detail by LaValle and Egerstedt [2007].

Cooperation and coordination In this work we consider only a single independent robot. We might also consider the performance of teams of cooperative robots on the same tasks. Such work would require an investigation of the joint I-spaces that would arise from the interaction of multiple agents, each having

only limited information. In particular, limited and possibly noisy communication between robots must be modeled. Many of the relevant issues are worked out in the game theory literature [Başar and Olsder, 1995, Owen, 1982].
